INTRODUCTION

Among human-made satellites working in orbit at significant altitudes above the Earth, geostationary (GEO) satellites are the most common. They have been the first commercial application to guarantee visibility between points on the Earth that are not in direct line of sight because of the Earth's spherical nature. For a long time, they have been the best and most economical way to allow international communications across the oceans. Currently, geostationary satellites represent also a useful complement to terrestrial facilities in order to complete the global information infrastructure in which every component (terrestrial cabled, terrestrial wireless, and satellite) must play the most suitable role to provide telecommunication connectivity (and hence services) anywhere and to anyone.

Geostationary satellites complement the terrestrial network infrastructure to complete the geographical coverage, to guarantee the *quality of service* (QoS) as a backup infrastructure (for example, in case of emergency), to supply fundamental overlay functionalities, and to deliver high-quality broadcasting and multicasting services at competitive prices.

This chapter provides general considerations on geostationary satellites and services; describes satellite system characteristics in terms of architecture, physical layer, security, and standards; deals with interoperability with terrestrial systems; describes two milestone systems; gives an overview of the major commercial systems; and finally draws conclusions.

USE OF GEOSYNCHRONOUS SATELLITES FOR FIXED SERVICES

A geosynchronous or geostationary satellite acts as a radio relay in the sky. It receives signals such as voice, data,

facsimile, and video from stations located on the Earth, amplifies these signals, and sends them back to other Earth stations.

These satellites are placed in *geostationary* or *geosynchronous* orbits at an altitude of 35,786 km (22,282 miles) (Maral and Bousquet 2003). They appear to be stationary with respect to a point on the Earth because they travel around the Earth in exactly its rotation time. In principle, only three satellites in geostationary orbit above the equator are sufficient to cover the entire Earth except for uninhabited polar regions.

If one hop on the satellite is not sufficient to reach the final destination, for a pure satellite global network, signals must be relayed through a second satellite, thus requiring either a double hop or an intersatellite link.

SOME CONSIDERATIONS ON SATELLITE SERVICES

Fixed satellite services are related to all of the links with stations, with either bidirectional or one-way capability, in stationary conditions (thus including transportable stations). Nevertheless, this concept is somehow flexible because the same satellite infrastructure can deliver both fixed and mobile services (e.g., the Omnitrac service for truck localization working at 11–14 GHz). Moreover, the growing use of data and multimedia communications makes the difference even more thin. In any case, thanks to the limited dimensions of current satellite traffic stations, they are strongly utilized for fixed, nomadic, and, thanks to the steering capability of modern antennae, mobile communications (not handheld terminals).

During the last ten years, the traditional use of satellite communications strongly evolved from trunk services across the oceans to more innovative systems based on

the TCP-IP protocol and multimedia applications in those areas where satellite technology remains highly competitive. In particular, satellite networks and architectures are highly competitive and cost-effective, in addition to classical broadcast and remote area communications, in the emergency operations (including telemedicine, operating team support, etc.), for providing backup infrastructures and overlay network and supporting interoperability with different terrestrial subnetworks. The need for more capacity and bandwidth is satisfied by the use of high frequencies (as high as 30 GHz and more), allowing the use of small antennae that are available at low cost and acceptable reliability.

In recent years, dual use applications for telecommunications satellites are becoming popular (e.g., military and civilian, commercial and governmental). Satellites are essential for security, safety, and defense, but exclusive use of the capacity for institutional markets needs an extremely long time for the investment to break even, whereas the combination of high-quality commercial (typically, business to business) and institutional applications can make investment in satellites more attractive.

All of the major satellite operators and service providers offer satellite capacity to both institutional and commercial customers. The possibility of delivering secure and robust communications peer to peer is the key characteristic of the service.

SATELLITE SYSTEM RATIONALE

The use of satellites is appropriate to meet the following objectives: cost effectiveness, emergency management, quick setup, large coverage, flexibility, and enhanced connectivity.

- **Costs:** The advantage in terms of cost is that it is independent of distance (with one-satellite coverage) and is efficient and effective for collecting, broadcasting, and multicasting.
- **Emergency:** In case of emergencies or disasters, when terrestrial infrastructures can be out of order, satellites offer a unique service.
- **Setup:** Satellite networks are characterized by relatively short deployment time and easy setup activities.
- **Coverage:** Satellites offer coverage for large areas and ensure long-range mobility, and they can bypass highly crowded terrestrial networks.
- **Flexibility:** Satellites can offer a high degree of flexibility in terms of both architecture and resource management.
- **Connectivity:** Satellites can constitute both a backup network and an overlay network, and they guarantee service in areas with scarce or no infrastructure.

Architecture

Orbit and Orbit Control

In celestial mechanics, the term *orbit* defines the motion of a satellite in the presence of gravity. This orbit cannot be modified from its spontaneous evolution, which depends on the initial conditions and the presence of

nongravitational forces and fields. In the case of astrodynamics, the dynamic behavior of satellites can be driven and commanded toward a defined state. The control of the trajectory phase is fundamental in space flight.

Trajectories are controlled by means of propulsive devices (thrusts) in order to achieve the final orbit objective, starting from an initial state. This control respects a set of constraints between the initial and the final state, matching defined flight performance objectives. The overall trajectory is composed of sequences of arcs with thrust switched on and sequences of arcs with thrust switched off (known as the *thrusting* and *coasting arcs*, respectively).

The orbit is characterized by the *orbit elements*, a set of independent variables that completely define the orbital motion of a satellite schematized as a test particle (Tirrò 1993). Six variables are needed to define the orbit completely, and the motion can be described via the motion of the *mass center* of the satellite. The state equations (a set of nonlinear ordinary differential equations) are used to describe the orbit element time evolution. To explicitly obtain the satellite motion, the state equations must be numerically integrated; the choice of the initial set of independent variables depends on the class of flight considered. The most common orbital sets are the Keplerian element, spherical coordinates, the equinotional set, and Cartesian variables. Keplerian coordinates are preferred for elliptical orbits.

Two variables define the ellipse form: (1) the semimajor axis and (2) eccentricity (e), the ratio between the focal distance and the major axis. When $e = 0$, the orbit is circular.

Three variables define the orientation of the ellipse in the space:

1. the *inclination angle* (i), which is the angle between the plane containing the orbit and a reference plane such as the equatorial one in the case of Earth;
2. the *ascending node right ascension* (Ω), which is the counterclockwise angle between the vertical equinox direction and the line defined by the orbital plane with the reference plane on the side of the motion of the satellite from below; and
3. the *perifocus argument* (ω), which is the counterclockwise angle along the orbit between the ascending node and the perifocus point of minimum distance from the dynamical focus of the ellipse.

The last variable is the position of the material point on the orbit at the given epoch. This is usually called the *true anomaly* (η), and it measures the counterclockwise angular distance between the perifocus and the position of the material point on the orbit.

The geostationary and geosynchronous orbits are ideally those circular orbits for which the motion period of the satellite around the Earth is equal to its rotation period. When the inclination angle is equal to 0 degrees, the orbit is called *geostationary*, and the satellite looks fixed with respect to the Earth. Otherwise, the orbit is called *geosynchronous*, and the satellite is moving essentially up and down the equatorial plane on a narrow eight. The radius of a geostationary orbit is 42,164 km, and the period is 86,164 s.

In practical cases, the following factors contribute to making the geostationary orbit unstable without control:

- the nonspherical shape of the Earth,
- radiation pressure (resulting from solar light), and
- attraction on the satellite resulting from the gravitational fields of the sun, moon, and other celestial bodies.

The satellite motion, when it has reached the final orbital position as shown in Figure 1 (which also shows all of the intermediate phases), is controlled using the suitable frequency communication band by a telemetry, ranging, and command center that keeps the satellite in place with an accuracy given by an angular box (typical sizes are within 0.05–0.1 degree for the three angles of roll, pitch, and yaw), keeping it pointed on Earth and thus minimizing propellant consumption.

A satellite system can be divided into two main segments: the space segment and the Earth segment. The general architecture is presented in Figure 2.

Space Segment

The space segment (Figure 3) can be roughly divided in the following subsystems: the structure; a power section (batteries and solar panels); a stabilization and propulsion section (including propellant); a *telemetry, telecommand, and control* (TT&C) section to remotely control the spacecraft's on-board motors; the thermal control; the on-board data handling; and a payload section that exploits communication between two Earth stations.

The payload architecture can be transparent if it acts as a bent pipe (just change the frequency and amplify signals), or it can be regenerative if it implements some *on-board processing* (OBP) features, which means that it

Figure 1: Orbital transfer phases to the geostationary final position (courtesy of Telespazio)

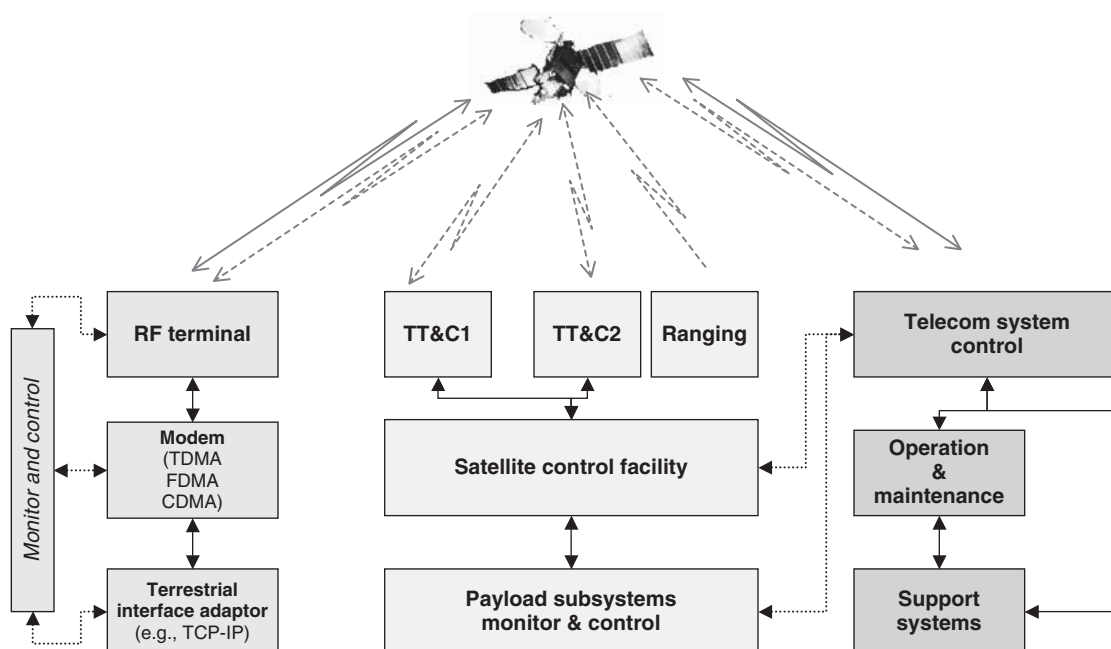

Figure 2: Satellite system general architecture

Figure 3: Space segment—Artemis (courtesy of Telespazio)

must at least demodulate and remodulate signals separating the uplink from the downlink. It can also decode signals, change polarization, interconnect beam to beam, route packets, and switch messages. On-board switching can be implemented at either baseband or microwave frequencies.

Currently, three types of on-board processing operate in the geostationary orbit:

1. *on-board processing* with full termination of the uplink at the baseband level;
2. *SkyPlex technology* in which the uplink is oversampled at the baseband level without analysis of the connectivity information and the downlink is a *pseudo-time division multiplexing (TDM)*; and
3. *trans-lucid technology* in which the uplink is oversampled at the baseband level and the downlink consists of separate channel for each transmitted circuit.

An important part of the payload is the antenna subsystem. GEO satellites need large antennae to concentrate the radiated field on the coverage areas of interest on the

Earth. On-board antenna size ranges from 15 meters for modern mobile communication satellites operating at L band, to 4–5 meters for those working in C band, and to 2 meter or less for those working at K_u and K_a bands.

To increase satellite capacity, antennae with multi-beam capability (either fixed or steerable) are adopted. In such a configuration, frequency and polarization reuse and contoured beams limit the radiation on the area of interest, oversizing the antenna diameter and using a feed cluster to illuminate the reflector.

Frequency Bands and Coverage

The fixed satellite services have dedicated frequency bands according to the geographical region of coverage as established by the International Telecommunications Union (ITU) (Figure 4).

Because of the limitations of the geostationary orbit (which is unique), each bandwidth allotment at the national level implies several characteristics, such as the nominal orbital position and the flexibility of this position defined by the predetermined arc, the bandwidth, the service coverage, the *equivalent isotropic radiated power (EIRP)*, the density of the satellites over the arc, the power spectral density, and the Earth station position. Practical difficulties with existing systems, however, have created several exceptions to a fully regulated system. For the purpose of frequency allocation, the world is divided into three regions as shown in Figure 4. The frequency allocation in the three regions is presented in Figure 5.

Efficient Use of the Geostationary Orbit and Spectrum Resource

Because of its unicity, the geostationary orbit can be overcrowded. As a consequence, it must be considered a natural resource and its shared utilization must be

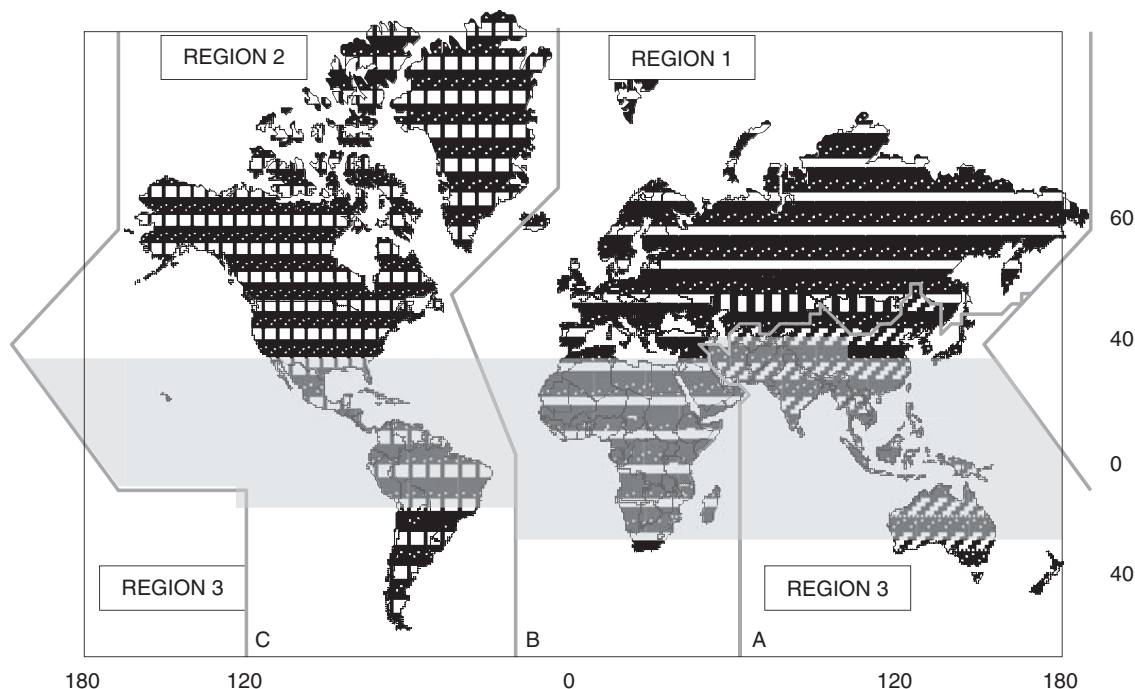

Figure 4: World frequency zones

Figure 5: Uplink and downlink frequency allocation for the three world ITU regions

carefully optimized, and it is regulated by international bodies. In this respect, two problems in particular must be considered: the probability of two satellites colliding (considering the number of active and abandoned satellites) and the presence of damaging space debris. The probability of such catastrophic events has been evaluated as approximately 1 in 1 million.

Another problem concerns *radio frequency* (RF) blockage resulting from the transition of lower orbiting satellites with respect to the GEO ones. The probability of these events is some 1000 times larger than collision, but of course the impact in terms of loss of transmitted data is limited. Nevertheless, the main limitation is related to the available frequency spectrum and the total available orbital arc (360 degrees). There are many methodologies to optimize the use of the geostationary orbit, optimizing the frequency reuse, the satellite control box (station keeping), and the interference level to and from other satellites and ground stations. In this respect, coordination procedures have been set up by the ITU, as mentioned in Luglio and Saitto (2006).

Ground Segment

The ground segment is typically composed of two sections:

1. The first, which is related to payload utilization, is composed of Earth stations and the *network operation center* (NOC); and
2. the satellite operation control, which comprises the monitoring and control center, the TT&C station, and ranging stations.

The Earth stations can be of two types: gateway and user terminals (Elbert 2000). The gateway (Figure 6), usually a big station, is in charge of connecting the satellite systems with the terrestrial networks.

The user terminals (Figure 7) represent the physical devices through which users can access the satellite resources. They can be classified as *fixed* (*very small aperture terminals*, or VSATs), *transportable* (VSAT-like and mounted on a vehicle but working in stationary conditions), or *mobile* (handheld and cellular-like). Each terminal is equipped

Figure 6: A large Intelsat and a small GW (courtesy of Telespazio)

Figure 7: VSAT station (courtesy of Telespazio)

with a base-band section and an RF section. VSAT terminals can be connected in full mesh topology or in star topology. Terminals suitable to the mesh topology are more complex and expensive than those utilized for star networks.

The NOC includes the network control center, which is in charge of configuration management, capacity and bandwidth management, acquisition and synchronization control, performance management, alarm management, security management, billing, and accounting.

The satellite operation control (Figure 8) is responsible for maintaining the satellite in the orbital slot with specified accuracy (station keeping) and controlling and configuring all of the satellite subsystems via the TT&C Earth segment, which exchanges information with the TT&C section on-board and the ranging station (see Figure 9), which is used to accurately measure satellite position.

Network Topology and Connectivity

Two topologies are usually supported by a satellite network: star and mesh. The star topology (Figure 10)

consists of a central hub station and a set of user terminals, typically much smaller and consuming less power than the hub. The hub acts as the star center through which all of the traffic transits; as a consequence, every pair of

Figure 8: Satellite operation center

ADDITIONAL SUPPORT PROVIDED
VIA A SECOND RANGING STATION
LOCATED AT AN APPROPRIATE
LONGITUDE

Figure 9: Ranging station (courtesy of Telespazio)

user terminals is physically interconnected through the hub, thus needing a double hop on the satellite, increasing delay and use of the bandwidth. In this configuration, the network is characterized by two streams: the forward stream from the hub to the terminals and the return stream from the terminals to the hub.

In the mesh topology (Figure 11), the user terminals can be directly interconnected among one another, needing only one hop on the satellite, and thus minimizing the use of the bandwidth and the delay. In recent years, in order to allow mesh topologies without using large antennae, satellites have payloads that integrate on-board processing and nontransparent architectures. Also hybrid topologies are allowed, although they have trade-offs in performance.

The Physical Layer

The physical layer concerns the capability to establish, to ensure, and to keep physical connectivity, taking into account propagation channel characteristics and the capability to produce power on-board. In fact, the propagation channel is characterized by meaningful nonlinearity that strongly affects technical choices. Physical layer issues are more extensively presented in Luglio and Saitto (2006), but three aspects—antennae, link budgets, and synchronization—are dealt with here, particularly those aspects related to geostationary satellites.

Antennae

Satellite on-board antennae have the major task of radiating and receiving energy to and from the areas of interest. The antennae on the first missions provided global coverage of the Earth region visible from a satellite (approximately a cone of 8 degrees aperture angle). The new satellite antennae can be designed to have contoured

Figure 10: Typical star topology (courtesy of Telespazio)

Figure 11: Typical mesh topology

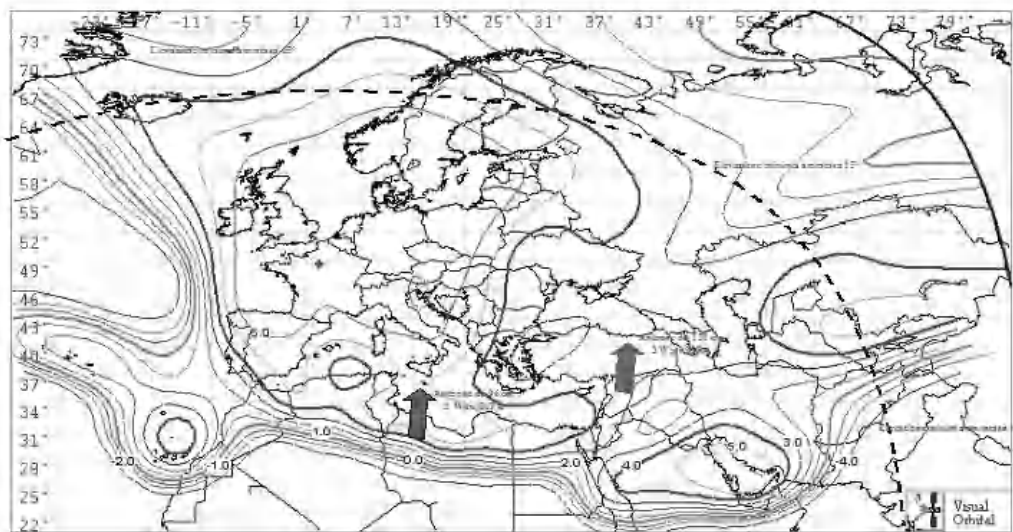

Figure 12: W3A Eutelsat at 7° east contoured beam coverage (courtesy of Telespazio)

or multiple beams to cover as far as possible strictly the region of interest with the best transmitted EIRP on the downlink and the best gain over noise temperature ratio on the uplink (Figure 12).

Earth antennae have two main functions. They provide gain (essentially the capability to concentrate the

radiated energy in a cone with respect to omnidirectional radiation) and also limit the radiation into confined regions of space delimited by the antenna beam. These properties are largely dependent on the antenna size, used frequencies, and technology (reflector, array, single beam, multiple beam, etc.).

For a circular, dish antenna, the gain G is related to the antenna area A by the formula:

$$G = \eta 4\pi A / \lambda^2$$

where η is the antenna efficiency (typical values between 0.6 and 0.7 for parabolic aperture dishes) and λ is the wavelength ($\lambda = c/f$, f being the frequency and c the light speed). The half-power beam width is given by the approximate relationship

$$\theta_{3dB} \approx 70\lambda/D \text{ (degrees)}$$

being θ_{3dB} the half-power beamwidth and D the antenna diameter. Therefore, high gain and narrow beams are strongly correlated. For $\eta = 0.5$:

$$G \approx 24000/\theta_{3dB}^2$$

The cost of an antenna is strongly dependent on its diameter. The diameter and the accuracy have a meaningful effect not only on the gain, but also on the near and far side lobes, which are the main cause of interference among different satellites and with terrestrial systems. The trend toward using higher frequencies is also justified with increased directivity with the same antenna size.

Link Budgets

The design of a satellite network is based on the results of the relevant link budget. The link budget will determine the main characteristics of the system such as size of the antennae to use, power requirements, link availability, *bit error rate* (BER), and eventually overall customer satisfaction. The parameters of a link budget and the involved mathematics are relatively simple to support preliminary estimation of end-to-end system performance.

The modeling of each component of the link budget—such as the uplink power amplifier gain and noise factors, transmit antenna gain, slant paths and corresponding atmospheric loss over distance, satellite transponder noise levels and power gains, receive antenna and amplifier gains and noise factors, cable losses, adjacent satellite interference levels, and attenuation caused by the troposphere—must be carefully evaluated, increasing the accuracy as far as the design is running and optimizing the overall performance via optimization procedures. In particular, attenuation, because of the presence of the troposphere, is mainly determined by rain, gas, clouds, and scintillation; as such, it can be characterized only statistically (Luglio and Saitto 2006). Rain represents the most significant factor; its contribution mainly depends on frequency and terminal location. In fact, the absorption of rain drops depends on the former, whereas the latter is correlated to rain intensity, which is statistically uneven in geographic distribution, and determines the slant path length inside the troposphere.

In general terms, the link budget can be considered for two classes of transponders:

1. *transparent* transponders in which the uplink *carrier-to-noise ratio* (CNR) is directly related to the down link CNR; and

2. *regenerative* transponders in which the uplink CNR and the downlink CNR are independent.

In the first case, the overall CNR $(N_0/C)_{tot}$ is given by

$$(N_0/C)_{tot} = (N_0/C)_{up} + (N_0/C)_{dw} + (N_0/C)_i + (N_0/C)_{in}$$

where N_0 is the noise power density, C is the carrier power, and up , dw , i , and in are the respective ratios for the uplink, downlink, co-channel interference, and transponder intermodulation.

In the case of the regenerative transponder, the contributions are independent and the overall performance is evaluated by the bit error rate, $(BER)_{tot}$:

$$(BER)_{tot} = (BER)_{up} + (BER)_{dw} + (BER)_{in} + (BER)_{iup} + (BER)_{idw}$$

Synchronization Issues for TDMA Access

Synchronization is an essential aspect of digital satellite communications. Because *time-division multiple access* (TDMA) is the most utilized multiple access scheme in satellite fixed communications, synchronization issues are presented only for TDMA.

The choice of synchronization system is a function of the satellite system architecture. In general terms, synchronization is a complex estimation process that allows the general characteristics of the transmitted signal (e.g., frequency and phase of the transmitted carrier, clock and frame synchronization of the transmitted sequence) to be recovered at the receiving side. TDMA and on-board processing TDMA require highly sophisticated synchronization procedures, which may include satellite position and ranging measurement in the case of multiple beam operations, when a transmitting station cannot receive a burst transmitted by itself. In addition to carrier and bit synchronizations, which are similar to other communication systems, satellite TDMA systems require the transmission of a synchronization sequence, the correlation at the receiving station with itself, and the implementation of an acquisition and synchronization procedure, which allows the shortest and best performing bit sequence to maximize the efficiency of the TDMA burst.

The satellite movements around its nominal position imply periodic fluctuations of the clock and the need for suitable buffers of the Earth stations at the interface with the terrestrial networks to avoid losses of information. In addition to this orbital effect, satellite communications need synchronization among different stations positioned in wide areas of coverage, with or without the possibility of the transmitting reference station seeing its own transmitted signal (Figure 13) (Wu 1989).

In case the reference station can receive its signal, the synchronization of the frame and bursts can be determined by only one reference station; when the reference station cannot receive its signal, a second station in the receiving spot coverage is necessary to complete the synchronization loop. The clock and frame synchronizations are therefore peculiar to the satellite system. For TDMA systems, the RF channel is utilized by only one of the stations sharing the channel. Each station is allowed to periodically transmit limited duration bursts into the channel,

Figure 13: Synchronization schemes for transmission station visible or not visible by itself

leaving the rest of the frame to the other stations. Thus, it is mandatory to schedule the time for all of the stations on the same time and frame reference. To this aim, the reference station distributes the *start of frame* (SOF) burst to all stations included in the system. Each station is permitted to transmit in a specific frame window that includes time allowance for avoiding collision between adjacent bursts. The SOF contains a portion dedicated to carrier and bit timing recovery and is marked by a *reference unique word* (RUW). Received by all stations, the RUW is used to evaluate the reference time for all of the traffic bursts transmissions from each transmission station.

Traffic bursts are characterized by a structure similar to the reference burst called the *preamble* that carries the user information part (traffic data). The traffic data are typically of variable length, whereas the preamble is composed of four sections:

1. The first section is dedicated to carrier and bit timing recovery synchronization.
2. The second section is the *unique word* (UW) necessary for phasing the position of the burst and solving potential ambiguities of the sequence (the UW and the RUW are often derived from the same bit sequence to simplify the receiver HW configuration).

3. and 4. The third and the fourth sections are related to service channels for signaling transportation and orderwire, which is used by service providers to test QoS.

Figure 14 shows the general architecture of the TDMA burst format, including synchronization.

Security Issues

Satellite networks have an intrinsic security level supplied by the need to synchronize access (TDMA and CDMA techniques), which is a function managed by a complex hub. In addition, satellite networks can include cryptography devices for public and private keys.

It is important to briefly analyze the impact of encryption on satellite transmissions. Cryptography is based on the application of an algorithm to the transmission, which is based on the knowledge of the activation keys. This knowledge is limited to the end nodes of the encryption process. The strength of the encryption algorithm is a function of its complexity and is evaluated on: (1) the basis of the number of operations necessary to break it and (2) the not yet discovered set of rules to break it.

Complexity plays a negative role for real time encryption of high data rate stream. The encryption key can be

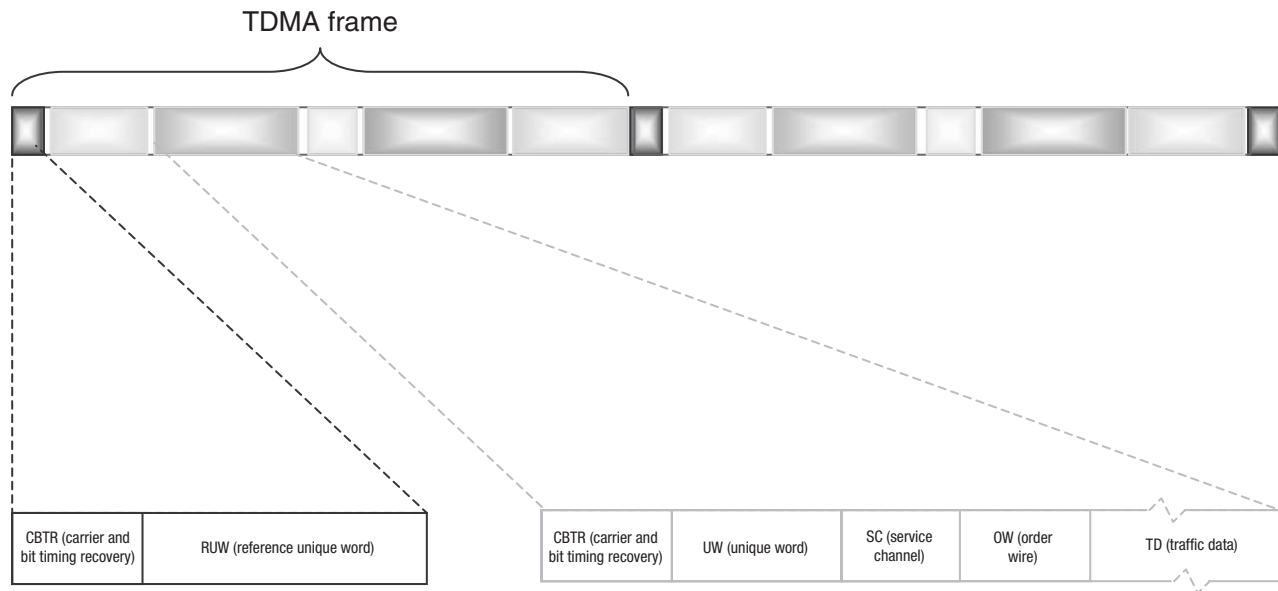

Figure 14: TDMA frame architecture and synchronization RUW and UW

private or public. In the former case, the key is distributed to the authorized correspondents. The key information, updated periodically, is an extremely delicate phase of the overall encryption process. In the latter case, from the generation of two random numbers a public modulus is generated and a procedure is available to the correspondents to have access to the clear information.

The network system security should be guaranteed at both information and communication levels. The encryption can be introduced as a service at three different levels: (1) link by link, (2) node by node, and (3) end to end.

In the link-by-link case, security is managed from the user to the control center at each level of the network. In the node-by-node case, routers and switches are included in the protection level (secure communications are managed at the routing level). In the end-to-end case, the encryption protection is solved only at the final user destination, offering the maximum level of protection. When end-to-end encryption is not viable, the critical network nodes, where encryption algorithms are applied, shall be adequately protected.

One particular satellite encryption process is the point-to-multipoint transmission, which is popular for protecting TV broadcasting from potential intrusions. A list of the main encryption processes for TV satellites includes the following.

- VideoCrypt, originally English, works on *phase alternating line* (PAL) channels with two options: the original VideoCrypt, which should be used inside the United Kingdom and Ireland; and VideoCrypt II, which is meant for continental Europe.
- EuroCrypt was developed with MAC. Almost all MAC receivers have an integrated EuroCrypt decoder.
- Nagravision, also known as Syster, is mainly used in France for SECAM (*séquential colour avec mémoire*) channels, but is also used with PAL in Germany and

Spain. In France, it is used primarily by channels owned by the Canal+ network.

- Luxcrypt, which is used by the Dutch RTL4/V network, does not need a smart card.

Note that studies and investigation are ongoing to allow the combined use of low-orbit satellites (such as Globalstar and Iridium) and geostationary satellites to have an additional service channel with virtually no latency time to improve the overall performance of encrypted satellite channels. Security issues for satellite systems are more extensively dealt with in Luglio and Saitto (2005).

Examples of Standards

An overview on open standards is given in Luglio and Saitto (2006). In this chapter, two important proprietary standards—one for direct-to-users services and one for trunk services—are proposed: SkyPlexNet and Intelsat TDMA.

SkyPlexNet

SkyplexNet is a digital platform for broadband telecommunications that offers direct access to the satellite for interactive multimedia services: from distance learning to telemedicine, from Webcasting to videoconferencing and data transfer, from company intranet to thematic multicasting, and from the small office and home office (SOHO) to municipal networks for public services, including emergency management. The SkyplexNet network (see Figure 15) is based on SkyPlex, a digital processor that implements *digital video broadcasting over satellite* (DVB-S) baseband processing and channel adaptation on board the satellite instead of on the ground as in traditional systems. The payload may be considered somehow regenerative (in a broad sense) because it demodulates the upstream signal before entering the SkyPlex processor; in this way

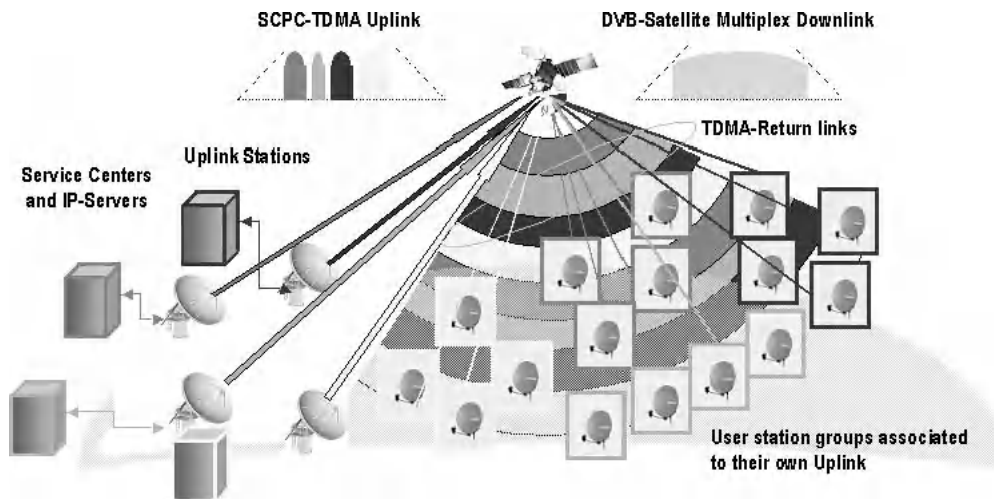

Figure 15: SkyPlexNet system architecture

providing larger flexibility with respect to traditional architectures. The new turbo SkyPlex is an improvement of the transponder carried on Hot Bird 5 in 1988 and is able to provide large flexibility in bandwidth assignment.

The main characteristics of SkyPlexNet are:

- bandwidth on demand,
- available bit rates from 512 kbit/s to 6000 kbit/s,
- connectivity on request,
- customized fare profile,
- compatibility with DVB-S (MPEG-2/-4), and
- uplink station diameter from 1.2 m to 2.2 m.

The available services are:

- digital broadcasting TV,
- business TV,
- video portals for business-to-business and business-to-consumer applications,
- audio and video streaming,
- audio and video streaming with terrestrial Internet,
- tele-education,
- multimedia content distribution on program mode and on request,
- asynchronous services for data delivery, and
- synchronous service delivery (video, audio and video, with Internet protocol, or IP, interactivity).

The main elements of the Earth segment are:

- the network operation center, which monitors and controls services, interfaces with the satellite operator, assigns capacities to users, and provides customer support;
- the customer service center, which manages contents and customer terminal interactions;
- the uplink station, which is in charge of connecting all of the network terminals of a specific customer and which transmits the uplink DVB MPEG to the satellite;

- the user terminal, which is composed of a small satellite station using a standard DVB receiver board and a SkyPlex transmission modem connected to a personal computer via an IP interface or to a satellite router if the interface is with a local network;
- the IP DVB gateway, which is the interface between the uplink station and the service center; and
- the service center, which manages the functionalities necessary to interface all of the elements of the network—in particular, user information gathering and billing, acquisition and elaboration of multimedia contents, data broadcasting and multicasting, session scheduling, bandwidth management, final user interfacing, access control, and uplink interface.

Intelsat TDMA

TDMA has been and is currently the multiple access scheme most utilized in satellite telecommunications. As a significant and general example, we will consider Intelsat TDMA.

The Intelsat TDMA transmission system has been active for more than thirty years. The system has endorsed continuous improvement and upgrading and has been the reference and the benchmark for several satellite TDMA systems (Freeman 1985). The introduction of the Hemi coverage with Intelsat VI has required the use of four reference stations (two for each area of Hemi coverage) because the reference station cannot receive its signal on the downlink channel. The general scheme of the operation of the reference stations for the two Hemi zones is shown in Figure 16.

Reference stations have the following main functionalities:

- determine satellite position for acquisition;
- provide open loop acquisition to traffic terminals;
- monitor TDMA;
- manage network;
- provide common synchronization among different Intelsat satellites;

Figure 16: INTELSAT TDMA general reference stations and bursts architecture from INTELSAT VI

- provide voice, orderwire, and so on;
- provide access to the Intelsat operation center;
- generate and receive bursts with housekeeping information; and
- perform transponder hopping when necessary and possible.

The presence of one reference station for each Hemi is needed for visibility reasons (the signal from each station is directed to the other beam so that each station does not receive its own signal), whereas the presence of two reference stations for each Hemi is for redundancy. Even if both reference stations are active for each spot, the traffic terminals respond only to the primary station; the secondary station replaces the primary only in cases of failure.

The nominal time guards between the primary and the secondary reference bursts are of sixty-four symbols. The reference burst consists of a preamble and a *control and delay channel* (CDC). The traffic burst is composed of a preamble and a traffic section, consisting of at least one digital speech interpolator, and one section called DNI (Digital No Speech Interpolator) sub-bursts.

The unique words are composed of twenty-four symbols divided into two patterns of twelve that define position with respect to the start of the frame. Twelve symbols are used to solve the fourfold phase ambiguity because of the *quadrature phase shift keying* (QPSK) modulation scheme. The other twelve symbols define whether the UW is relative to the reference or the traffic burst.

The service channel is transmitted over the TDMA multiframe (consisting of sixteen frames) with a strong redundancy (one bit is repeated eight times in each burst). The CDC assigns the transmission time to the traffic stations. Transponder hopping is the ability of the traffic stations to hop across a maximum of four satellite transponders to increase the system efficiency.

The Intelsat TDMA characteristics are summarized below:

- frame period of 2 ms;
- burst transmission bit rate of 120 Mbit/s;
- nominal clear sky BER of 1×10^{-10} with FEC BCH 7/8 applied to the payload;
- QPSK with coherent demodulation phase-locked to the TDMA system clock;
- operates in any satellite beam coverage type (assignments set by Intelsat); and
- performance monitoring of uplink and downlink data displayed with time-indexed BER graphs and G.826 charts.

INTEROPERABILITY WITH TERRESTRIAL SYSTEMS

Satellite systems can play a fundamental role as an overlay network, interoperating with terrestrial infrastructures,

working as a backup or backbone connection, complementing coverage, and ensuring service continuity and long-range mobility. We briefly introduce this concept with particular regard to two scenarios: the WiMAX standard and MANETs.

Interoperability with WiMAX

The *worldwide interoperability for microwave access* (WiMAX) standard, also identified as IEEE 802.16, is proposed to offer broadband wireless access to telecommunication networks. The cellular-like architecture allows interconnection of different base stations in both point-to-point mode and mesh modes, providing as much as 70 Mbit/s capacity per station.

WiMAX will provide fast Internet access and voice and video distribution services even for *no line of sight* (NLOS) environments and mobile users. These target characteristics make the system highly attractive for different market segments (both residential and business users) and geographical areas (developing countries, rural areas, and densely populated areas). Both the characteristics and the potential markets suggest that WiMAX will provide the best performance and ensure business continuity when implemented with an integrated infrastructure to interoperate with satellite systems, which assume a critically important role in such scenarios and for such applications.

In fact, satellite systems offer the technological element that can assist the WiMAX network in providing high QoS. In particular, satellites can be used to interconnect a set of base stations where no or poor terrestrial infrastructures are deployed, to guarantee coverage contiguity and service continuity for long-range mobility, or to ensure backup in case of either temporary failure or overflow of terrestrial networks. Moreover, because satellites assume a critical role in cases of emergency when terrestrial infrastructures can be seriously damaged (e.g., earthquakes, storms, terrorist attacks), it can guarantee service continuity and connectivity with remote networks or remote locations to a WiMAX network, which is likewise suitable to such scenarios. Furthermore, the two systems can reciprocally fill one another's service gaps: WiMAX as an in-building or shadowing areas gap filler for satellite and satellite as a coverage gap filler for WiMAX in uncovered areas. Finally, the integration of the two systems can help to guarantee security and safety services for monitoring and surveillance. Studies addressing feasibility assessment of an integrated infrastructure have obtained meaningful although preliminary results (Luglio, Mazzenga, and Corazza 2006a, 2006b).

Interoperability with MANETs

Mobile ad hoc networks (MANETs) are characterized by their intrinsic ability to be set up without needing any kind of infrastructure, which allows a high degree of flexibility at both the technological level and the application and service level. For this reason, they are particularly useful in environments where no fixed network infrastructure is available. For this reason, this technology is suitable for

emergency application, for example, when fixed telecommunications infrastructures are seriously damaged or destroyed.

Also, satellite networks work without terrestrial infrastructure, excluding one gateway localized inside the footprint, and they are easy to set up. For the same reasons, satellites can be fruitfully utilized in case of emergency.

Nevertheless, these two technologies are not in competition, as they might appear, but are absolutely complementary. In fact, MANETs are characterized by low consumption, limited capacity user terminals, and, most important, their ability to work in an extremely limited coverage range. On the contrary, satellite systems work with medium and large dimensions, with medium- and high-power user terminals, and over extremely wide areas of coverage. Moreover, MANETs are suitable for indoor environments, whereas satellite systems cannot work in NLOS environments.

Investigation has been performed on how to implement an integrated system composed of a satellite segment and a MANET, in which each segment plays a complementary role with respect to the other, with the aim of improving the degree of service (Luglio et al. 2006).

Interoperability with Data Networks

As already mentioned, geostationary satellite systems can play a fundamental and sometimes irreplaceable role in providing connectivity, especially in specific scenarios. As concerns the use of such systems for data transfer, pursuing interoperability with terrestrial data networks is particularly meaningful. In fact, data networks are characterized by peculiar requirements such as high capacity to allow fast transfer of huge amount of data, as well as the use of specific protocols (e.g., TCP/IP) to ensure reliability. To achieve easy interoperability, the satellite component must be compliant with such requirements.

For capacity requirements, at the physical and MAC layers geostationary satellite systems are quite compliant for network-oriented solutions (up to some hundreds Mbit/s using big stations); with user-oriented solutions, they can reach either some tens of Mbit/s with proprietary standards based on full mesh or star topology and the use of VSAT stations (up to 2.4 m of diameter) or 45 Mbit/s in the forward link and typically up to 2 Mbit/s in the return link with the *digital video broadcasting return channel via satellite* (DVB-RCS) standard. The use of DVB-S can apply only to the forward link in case of one-way (over satellite link) systems such as DVB IP, being the return link implemented via terrestrial fixed networks (PSTN, ISDN, etc.).

As for network layer requirements, the use of typical reliable transport protocols (e.g., TCP/IP) means significant performance degradation because of the conspicuous latency derived from the great distance between the Earth and the satellite. Nevertheless, performance degradation can be mitigated adopting technical solutions specifically designed for satellite systems, acting either at the flow control or the architectural level. Both aspects (the physical aspects related to the use of DVB-RCS and transport protocol adaptation) are addressed in Luglio and Saitto (2006).

MILESTONE SYSTEMS IN THE K_a BAND

Several steps in satellite communications history have been meaningful milestones either in terms of technology innovation or service evolution, as briefly highlighted in Luglio and Saitto (2006). The available room in this chapter prevents us from providing details on each of these systems. Thus, we have selected two systems that represent the last real milestone in terms of both technology (use of the K_a band, OBP, multibeam antennae, steerable antennae, and switching on board) and services (direct to user, VSAT, mobile services, emergency).

ITALSAT

ITALSAT was a satellite-based telecommunication system developed by Agenzia Spaziale Italiana (ASI), the Italian space agency. The satellite was successfully launched in January 1991 (Marconicchio, Morelli, and Valdoni 1992; Dinaro et al. 1998; Martinino et al. 1992).

On board there were two payloads for point-to-point and point-to-multipoint communications in the K_a band (20/30 GHz) with Italian coverage. The most important of these two payloads, having 0.9 Gbit/s capacity, provided a multispot (six spot) coverage, as shown in Figure 17, utilizing multibeam antennae with automatic pointing control, onboard coherent QPSK demodulation, and baseband switching with emitter-coupled logic gate array technology.

The other K_a band communication payload had three (36-MHz) transparent transponders and a global coverage antenna (Figure 18). The satellite embarked also another

Figure 17: Multibeam coverage example (IT ALSAT F1 and F2) (courtesy of Telespazio)

Figure 18: ITALSAT "global coverage" at 20–30 GHz

Figure 19: Propagation coverage at 20–40 and 50 GHz

payload in the EHF band (40–50 GHz) with European coverage for propagation experiments (Figure 19).

With the multibeam payload, the coverage was obtained with six spots (two groups of three) utilizing two independent antennae pointed toward the desired direction with a tracking system that ensured an overall error less than 0.003 degree. Each spot had the same number of carriers on both links. The total capacity was 12,000 32-kbit/s circuits (2000 for each spot). The carriers were QPSK-modulated at 147 Mbit/s. Each spot was served on-board by a single regenerative repeater, and the interspot connectivity was provided by a synchronous baseband space-switch matrix.

The main services offered were voice and data communication and television dissemination. The multibeam system was designed to be "network-oriented": Its Earth terminals were conceived to interface the terrestrial public network at its lowest hierarchical level, providing flexibility by offering its capacity in both semipermanent (i.e., changeable within a few minutes) and on-demand modes.

The ITALSAT system was conceived to perform different levels of network functions. In addition to the transmission and traffic arrangement functions, these functions allowed different types of traffic concentration. The ITALSAT network interfaced the terrestrial network by means of three kinds of stream: (1) 2 Mbit/s (trunk), (2) 2 Mbit/s stream split into individual four channels groups (split), and (3) streams with channels assigned on demand (*demand assigned multiple access*, or DAMA). Each of the six spots was designed to accept as many as sixteen but no more than sixty-four terminals (a traffic station is shown in Figure 20).

The access to the satellite was *TDMA satellite switched* (SS-TDMA) with a 32-ms frame. The six signals received on board were coherently demodulated and synchronously regenerated. Thus, the system was a *baseband SS-TDMA* (BB-SS-TDMA) type in the uplink and TDM in downlink.

The global national coverage payload had access to all points of the national territory, also offering emergency connections with disaster-hit areas and TV signal broadcasting. The coverage of the Italian territory (including islands) was obtained by means of a single antenna with a beamwidth of 1.06 degrees \times 1.55 degrees.

The payload included three transparent transponders, each with a 36-MHz bandwidth. Each transponder was compatible with the following types of access and modulation: QPSK-modulated digital signals with continuous access to the satellite at 24.576 Mbit/s; analogue signals such as standard TV signals, frequency modulated

Figure 20: ITALSAT 5-m traffic station (courtesy of Telespazio)

(FM-TV) with a 27-MHz bandwidth; and signals with multicarrier digital modulation (single channel per carrier, frequency division multiple access).

ACTS

Advanced Communications Technology Satellite (ACTS) was an experimental system developed by NASA for verifying advanced technology in the K_a band (Gedney, Schertler, and Gargione 2000; Gedney et al. 1992). The satellite weight was approximately 1500 kg and measured 14.1 m from tip to tip along the solar arrays and 9.1 m from one antenna to another. Separate K_a -band antennae were provided for transmitting and receiving signals.

The multispot coverage was obtained with two hopping beams (east and west) and three fixed beams. East and west spot beams were discriminated by polarization (vertical and horizontal). Hopping beams were able to hop to many locations, dwelling long enough at each to pick up the offered traffic, even in case of nonuniform demand for traffic, at the price of greater technological complexity than the fixed beams. ACTS also had a mechanically steerable antenna that was able to be pointed anywhere, even outside the continental United States (Alaska and Hawaii). All of the beams are interconnected on board. The access technique is DAMA-TDMA.

The ground segment included the NASA ground station, a spacecraft control center, and different kind of experimenters' terminals. The interconnection on board was performed either by a baseband processor or by an IF switch matrix. The baseband processor, dynamically programmable, interconnected the two hopping beams and operated on on-board stored baseband switched TDMA. In this case (low burst rate), the received signals were demodulated, decoded, routed on a circuit-switched basis, remodulated, encoded, and transmitted in the downlink beams. The microwave switch matrix interconnected the three fixed beams and operated in SS-TDMA. In this case (high burst rate), the matrix provided dynamic interconnection among the three beams.

OVERVIEW OF THE MAJOR COMMERCIAL SYSTEMS

Intelsat

Established in 1964 as the first commercial satellite services provider, Intelsat has more than forty years of experience in satellite communications (Intelsat, undated).

The Intelsat communications network is based on fifty-one (including the acquired Panamsat network) satellites in combination with terrestrial connectivity technology to allow enterprises, governments, and service providers deliver content around the world securely and reliably to residential and business users, also ensuring mobility (see Figure 21).

The main services delivered by Intelsat are the following.

- Capacity services: Flexible, diverse satellite coverage and capacity options for quality point-to-point or point-to-multipoint services.
- Global Connex managed services: Global, integrated satellite, and terrestrial network-managed services to meet broadband, trunking, and media requirements worldwide.

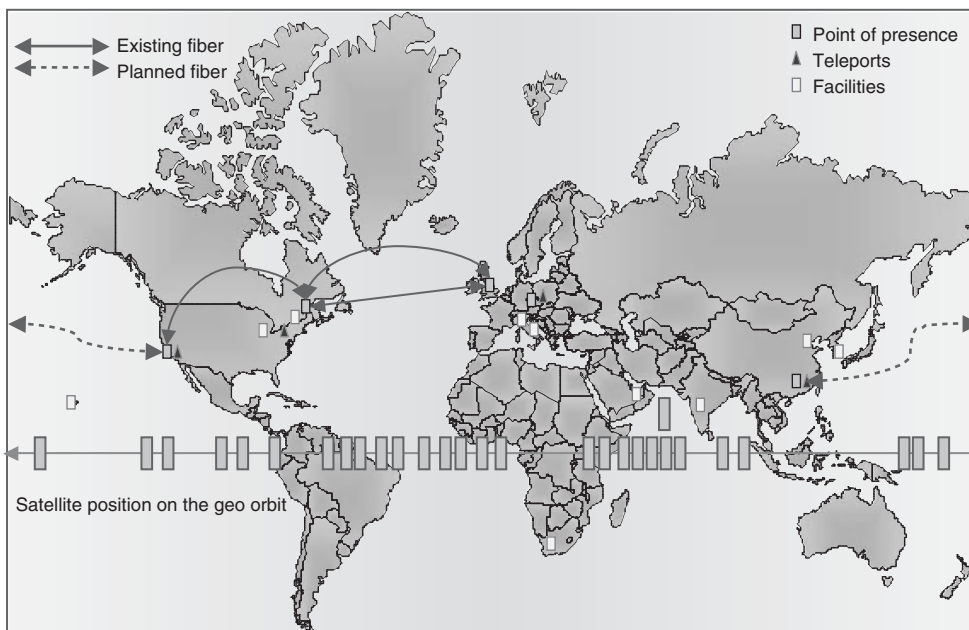

Figure 21: Intelsat satellite and terrestrial communication network map

Figure 22: The Fucino facility (courtesy of Telespazio)

- Specialized services: Value-added and specialized services, including disaster recovery, customer premises equipment programs, co-location services, and consulting and technical management, including support to satellite companies, organizations, and governments.

The twenty-eight geostationary-satellite global network is associated with ground stations, teleports, point of presence, and facilities. One of the largest stations is positioned at Fucino (Italy) which is shown in Figure 22. When satellites are operational, they are controlled from the control center in Washington, D.C., twenty-four hours a day.

Intelsat serves more than 700 customers around the world, including the world's largest Internet service providers, telecommunications companies, broadcasters, and corporate network service providers. Intelsat has offices in Brazil, China (Hong Kong), France, Germany, India, Singapore, South Africa, the United Arab Emirates, the United Kingdom, and the United States.

Intelsat provides solutions for access to or development of domestic and international networks. Satellites are also used for such diverse purposes as wide area network communication, cellular backhaul, Internet trunking, television broadcasting, and rural telephony. Intelsat is supplying systems everywhere with typical satellite performance.

The main milestones of Intelsat history are as follow:

- 1964 Launched the world's first commercial communications satellite
- 1969 First live global television broadcast of the Apollo 11 lunar landing
- 1974 Created the first international digital satellite voice communications service
- 1987 Linked 50,000 people in seventy cities for world's largest teleconference
- 1998 Established high-speed Internet backbone links around the world
- 2000 Compressed 40,000 hours of programming into two weeks for the Olympics Games in Sydney, Australia
- 2004 Intelsat becomes a private company after thirty-seven years as an intergovernmental organization
- 2006 Intelsat Ltd. acquires PanAmSat, controlling fifty-one satellites in geostationary orbit

Eutelsat

Eutelsat is another big satellite service and infrastructure provider (Eutelsat, undated). It commercializes capacity through twenty-four satellites that provide coverage over much of the world: from Europe to North Africa and the Middle East and from the United States to the Pacific Ocean and parts of Asia and Oceania. It serves more than 150 countries and more than 90 percent of the world's population. Eutelsat satellites offer a wide range of services: television and radio for public consumers, professional video services, networks for corporations, Internet services, and mobile communications. Eutelsat also has developed a set of broadband services for local, individual, and business communities, and in Italy it has opened an auxiliary point called Skylogic Italy to support services to wideband through multimedia platforms. Mainly from the orbital position of its Hot Bird satellites (13° east), Eutelsat transmits more than 1400 television channels to some 110 million of customers connected to a cable network or equipped for direct home reception.

Satellite and Services

Eutelsat satellites are positioned over the geostationary arc from the orbital position of 15 degrees west to 70.5 degrees east. The constellation is based on twenty-four satellites, twenty of which are managed completely by the company.

The Hot Bird family of satellites provides total coverage to Europe, part of Africa, and the entire Middle East. Approximately 100 million home customers are equipped to receive channels from Hot Bird satellites through the direct reception or via cable. The system provides more than 560 radio and multimedia services in the same area of coverage.

Eurobird satellites provide broadcasting and telecommunications services mainly to Central and Western Europe from the orbital positions of 28.5 degrees and 25.5 degrees east. Eurobird 1 provides continuity for telecommunication services (previously guaranteed from satellite Eutelsat II-F4), including business services, news distribution, and television and radio programs. The W series satellites serve a wide set of business users, including telecommunication companies, radio and television service providers, agencies of international news, industries, and multimedia services distributor. The W series is also the backbone network of the Eurovision and Euroradio networks for the exchange of television and radio programs at international level.

SESAT satellites (Siberia and Europe) provide a wide set of telecommunication services over a vast geographic area: from the Atlantic Ocean to eastern Russia, including a great part of Siberia. The satellites offer also military services in the Indian subcontinent through directional beams. Besides helping to develop new markets in Eastern Europe and in South Asia for all the types of telecommunication and business services, SESAT satellites guarantee also the inter-connection with Central and Western Europe. SESAT 1, at 36 degrees east (along with the satellite W4), contributes to the development of international, national, and regional services such as telephony and data services. SESAT 2, at 53 degrees east, distributes

telecommunication, broadband, and broadcasting services to Europe, Africa, Middle East, and Central Asia.

Eutelsat has placed a set of three Atlantic Bird satellites, named the "Atlantic Gate": Atlantic Bird 1 (K_u band, 12.5° west), Atlantic Bird 2 (K_u band, 8° west), and Atlantic Bird 3 (K_u and C bands, 5° west). Their main purpose is to offer a wireless connection between the Americas, Europe, Africa, and Western Asia. With twenty channels, Atlantic Bird 1 offers telecommunication services between Europe and America, connecting the two continents and providing a common virtual coverage. Like Atlantic Bird 1, Atlantic Bird 2 guarantees coverage with high power in the American and European areas, allowing the eastern coasts of the Americas to reach, directly across the Atlantic, Central and Western Europe and then the Persian Gulf. Atlantic Bird 3 satisfies the entire African area and market in the C band with ten transponders. The Atlantic Gate is suitable for video applications, IP, and data.

Eutelsat II satellites in inclined orbit offer solutions to the need for low-cost, short-term professional applications (e.g., news distribution) as well as Internet services. They are mainly used for the distribution of television and telecommunication services. Initially placed in orbits at 7 degrees, 10 degrees, and 16 degrees east, these satellites now occupy other orbital positions after being replaced by the newest W satellites. The services provided are public telephony, business applications, news distribution, and exchange of radio and television programs.

The e-BIRD satellite was launched in September 2003 at 33 degrees east to provide coverage to Europe and Turkey through four beams with high power and twenty-two transponders in the K_u band. The e-BIRD was the first satellite designed for broadband, two-way Internet services. Moreover, thanks to its position, it is able to offer broadband services also through small antennae.

SES Global

SES Global is a network of satellite operators providing service in every continent (SES, undated). They operate through SES Astra in Europe; SES NEWSKIES in the Middle East, part of Asia, South America, and Africa; and SES Americom in North America. They also participate with satellite operators AsiaSat, SES Sirius, Nahuelsat, and Star One. They offer global coverage with a satellite fleet of forty satellites that reach 95 percent of the world's population.

SES Global mainly provides the following services: media broadcasting, enterprise solutions, mobile broadband solutions, government services, and global solutions.

SES Astra Products and Services

The main services offered by SES Astra are as follow.

- **Broadcast services:** The analogue direct-to-home platform is one of the largest in the world. It provides more than 102 million home customers with access to 1600 radio and TV channels.
- **Broadband services:** Astra offers a large set of broadband products and services, including end-to-end solutions directly to users.
- **Services with direct cable:** This set of services allows cable operators to offer broadband Internet services, high speed, and low cost to customers in all of Europe.
- **Governmental services:** Astra provides satellite-based specialized telecommunications solutions (bandwidth, infrastructures, and network solutions) to governmental agencies, public administrators, and their contractors.
- **Technical solutions:** Astra is a partner for a large set of technical solutions to manufacturers in the satellite field, operators, and other types of customers involved in the engineering field.
- **Customer support:** Astra has created a series of individual packages for its customers, according to their individual needs.
- **Total solutions:** SES Global's companies and partners offer solutions for global access. Broadcast audiovisual or broadband IP content can be transmitted all over the world without cable through the Astra European hub.

SES Astra Constellation

Astra has a constellation of thirteen satellites. Seven are placed at the orbital position of 19.2 degrees east, three at 23.5 degrees east, and three more at 28.2 degrees, 23.5 degrees, and 24.2 degrees (see Table 1).

Satellites Astra 1KR, 1E, 1F, 1G, 1H, and 2C provide capacity mainly for the transmission of broadcast and broadband multimedia services. The main customers are those situated on continental Europe in correspondence with the orbital position of 19.2 degrees east.

Astra 3A and 1D are localized at 23.5 degrees east. Their main functions include supplying capacity for directed cable and improving multimedia services in wired

Table 1: SES Astra Satellites

Satellites at 19.2° east	Satellites at 23.5° east	Satellites at 28.2° east	Satellites at 37.5° east
Astra 1KR	Astra 3A	Astra 2A	Astra 4A

2000	AMC-7	137 W.L.	C-band	A2100A	Ariane 5G	North America; 50 states
2000	AMC-8	139 W.L.	C-band	A2100A	Ariane 5G	North America; 50 states
2000	AAP-1	108.2 E.L.	K _u	A2100AX	Proton K/Blok DM	China, Northeast Asia, South Asia

networks for corporate networks, occasional users, and business services.

The satellites Astra 2A, 2B, and 2D are placed at 28.2 degrees east and offer coverage for the United Kingdom and Ireland. These are used for direct-to-home services and mainly provide transmission capacity for broadcast and broadband multimedia services.

SES Americom Constellation

SES Americom has a constellation of twenty satellites. Table 2 shows the main characteristics of the constellation.

Hispasat

Hispasat is a Spanish company operating global satellite communications not only in the Spanish and Portuguese markets but also in the Americas, Europe, and North Africa (Hispsat, undated). Hispasat manages two orbital positions over the Atlantic region (30° west and 61° west) and operates with a constellation of three satellites (1C, 1D, and Amazonas), with one more in development (1E). It has a satellite control center near Madrid and two payload centers. The transponders of the Hispasat systems are mainly transparent (there is also an OBP Amheris payload), allowing the operators of satellite communications to transmit their different services using both analogue and digital connections.

Satellites

The Hispasat constellation is composed of four satellites. Hispasat 1C has a payload with twenty-four transponders with an operational capacity that covers both Europe and the Americas. This capacity supplies an operational level able to provide direct analogue or digital broadcast services.

Satellite Hispasat 1D was designed to provide the following services: broadcasting satellite services, fixed satellite services, television (U.S. market), and tactical and strategic networks for the Spanish Defense Ministry. Hispasat 1D is located at orbital position 30 degrees west uses twenty-eight transponders in the K_u band. Its scope is to guarantee continuity to the services provided from satellites 1A and 1B. Hispasat 1D also has a new spot on Central Europe improve the global connectivity.

Amazonas provides coverage of the Americas, Europe, and North Africa. At the same time, it complements the coverage of the Hispasat system over the western United States, including California. Amazonas will have a life of at least fifteen years. Its sixty-three transponders will operate in the K_u and C bands.

Satellite Hispasat 1E will provide multimedia services in the K_a band and will be able to exploit additional capacity in the K_u band to have a backup in orbit, which will be useful to strategic customers.

The Hispasat operator offers the following services and applications: television (direct to home broadcasting,

distribution, and contribution) and Internet, multimedia, and broadband (Internet backbone, high-speed Internet, and data and multicast broadcasting).

CONCLUSION

Fixed services that utilize geostationary satellite systems represent the major part of satellite operators' business: 95 percent or more. The utilization of satellites to provide telecommunication services represents a tiny niche market with respect to the entire telecommunication business but this niche is critically important for connectivity in remote areas and for communications in emergencies.

An overview of satellite systems characteristics, technology, services, and major operators was provided. More detail is available in the annex at the end of this chapter.

GLOSSARY

Dual Use: The use of facilities for both military and civil use.

Geostationary: Orbit around the Earth characterized by a revolution period equal to the Earth's rotation period.

Ground Segment: Component of a satellite system located on the Earth (wide sense).

Multispot Coverage: Capability of an antenna to produce more than one beam.

Payload: Component of a satellite that exploits telecommunications (in the strict sense).

Space Segment: Component of a satellite system located in orbit.

Transportable Stations: Earth stations that are easily transportable and lined up with the relevant geostationary satellite and operate as fixed stations.

Trunk Services: Telecommunication services characterized by high capacity.

Annex: Satellite Agencies

Agencies	Mission
Austrian Space Agency (ASA)	
Belgian Federal Science Policy	The missions of the Belgian Federal Science Policy office are exercised on three levels: scientific activities, technical activities, and cultural activities. The Department of Space Research and Applications of the Belgian Federal Science Policy office is in charge of managing the Belgian (public) participation in R&D activities carried out by industry and Belgian scientists in space-related matters. These activities are conducted primarily within the framework of the international organizations to which Belgium belongs (e.g., the European Space Agency and the European Organization for the Exploitation of Meteorological Satellites) or within the framework of bilateral agreements (e.g., with France on SPOT).
Brasil National Institute for Space Research (INPE)	
British National Space Centre (BNSC)	The BNSC is a voluntary partnership formed from ten government departments and research councils to coordinate UK civil space activity.
Canadian Space Agency/Agence Spatiale Canadienne (CSA/ASC)	
Centre National d'Etudes Spatiales (CNES)	French space agency
Comisión Nacional de Actividades Espaciales (CONAE) (Argentina)	Information on the Centro Regional de Datos Satelitales (CREDAS) and on Argentina's national space plan
Danish Space Research Institute (DSRI) (Denmark)	
Destination Earth (NASA)	The official Web site for NASA's Earth Science Enterprise
Deutsches Zentrum für Luft und Raumfahrt (DLR)	Germany's national aerospace center as well as the national space agency
European Space Agency (ESA)	
ESA Centre for Earth Observation (ESRIN)	One of four ESA establishments. Main activities: acquisition, archiving, and dissemination of data from Earth observation missions—in particular, ERS-1, for which it operates needed ground infrastructure. Main function: ESA data handling and dissemination center, being at the forefront of technologically advanced information systems.
European Space Operations Centre (ESOC)	ESA's satellite control center; responsible for the operations of all satellites and related ground stations and communications network.
European Space Technology Centre (ESTEC)	Noordwijk, the Netherlands; one of the three centers of the European Space Operations Centre
Finland National Technology Agency (Tekes)	National technology agency and main public financing organization for research and development in Finland. Coordinates and finances Finland's participation in ESA programs.
Indian Space Research Organisation (ISRO)	
International Space University (ISU)	Interdisciplinary, intercultural, and international institution preparing individuals to respond to current needs and increasing and evolving demands of space sector through multidisciplinary education and research programs
Italian Space Agency (ASI)	
National Academies of Science and Engineering (NASE) and National Research Council (NRC) Space Studies Board (SSB)	Advisory board within NRC, which is the NASE joint operational. Operates a number of standing committees and task groups that perform studies in space science and policy for the federal government.
National Aeronautics and Space Administration (NASA)	Ames Research Center (ARC)

National Academy of Sciences, Board on Physics and Astronomy (National Research Council)	
Netherlands Agency for Aerospace Programs (NIVR)	
Netherlands Space Research Organization (Stichting Ruimte Onderzoek Nederland, SRON)	Foundation within framework of the Netherlands Organization for Scientific Research (NWO). Initiates, develops, builds, and uses instruments for scientific research in and from space.
Norsk Romsenter (Norwegian Space Center)	Foundation cooperating closely with Ministry of Trade and Industry. Guides ESA contracts strategically. Public funds support development of industry, development and demonstration of space applications, and optimal conditions for national space research.
Romanian Space Agency (ROSA)	National public institution that coordinates and represents Romanian space program, mainly R&D components.
Space Research Institute (IKI)	As the leading organization of the Russian Academy of Sciences in the field of investigations of Outer Space, Solar System planets and other objects of the Universe, Space Research Institute (IKI) is primarily in charge of long-range planning and elaboration of space research programs of which a considerable part is performed within the framework of international space research cooperation.
Spanish Center for Development of Industrial Technology	Centro para el Desarrollo Tecnológico Industrial (CDTI) acts as Spanish delegation to ESA. Is responsible for follow-up participation of Spanish industry in European space programs.
Spanish National Institute of Aerospace Techniques	Instituto Nacional de Técnica Aeroespacial (INTA): national space agency
Swedish Space Corporation (SSC)	
Swiss Space Office (SSO)	Swiss government unit in interior ministry dealing with space affairs. Mission is to propose and implement Swiss space policy after approval by federal council. Coordinates tasks and works closely with national scientists and industries.

AN OVERVIEW OF SATELLITE COMMUNICATIONS

For almost half a century, satellite networks have provided long-distance communications services to the public switched telephone network (PSTN) as well as television broadcasting. These services are particularly justified by the large footprint coverage of the satellite; to date, there is no substitute for satellites, especially with regard to services such as broadcasting. For these types of services, a satellite acts as a communications repeater or relay (according to whether the transmitted signal is digital or analog, respectively) that communicates with ground stations and solves the problem of transmission of electromagnetic waves between different parts of the world that are not within line of sight of one another. A noteworthy achievement in satellite communications is the formation of the International Telecommunications Satellite Organization (INTELSAT), which in 1964 established systems and standards initially for fixed-satellite service and subsequently for broadcast services among nations (Jamalipour 1998).

In the 1980s, satellites were deployed for the first time in mobile telecommunications by providing direct communications to maritime vessels and subsequently aircraft. The first major development in this area was the International Maritime Telecommunication Satellite (INMARSAT) satellite system. INMARSAT started a new era of satellite communications, called mobile satellite services (MSS), in 1982. This organization used a geostationary satellite system using L band (1.5–1.6 GHz) to provide telecommunication services mainly to ships. In the first generation of MSS, INMARSAT defined five standards: Standard A (1982), Standard B (1993), Standard C (1991), Standard M (1992/93), and Aeronautical Standard (1992). Different worldwide telecommunications services including voice, facsimile, and data were considered in these standards. INMARSAT continues its worldwide services as one of the most reliable satellite communications systems.

Although INMARSAT remains the most distinguishable satellite system of its kind, there were other MSSs

developed during the first generation (1G) mobile satellite systems, such as services offered by QUALCOMM in North America (1989), ALCATEL QUALCOMM in Europe (1991), and the Japanese NASDA system (1987).

Reduction in size and cost of user terminals was the motive for second-generation (2G) MSS, which was started around 1985. In this generation, the interconnection of satellite systems with terrestrial wireless systems was also considered. INMARSAT defined its mini-M standard in 1995 with worldwide voice, data, facsimile, and telex service at 2.4 Kbps. American Mobile Satellite Corporation (AMSC), NSTAR of Japan, European mobile satellite (EMS), and several others are included in the second-generation MSS.

Geostationary orbit (GEO) satellite systems face unavoidably long propagation delay and large transmission power requirements. Consideration of small-size user terminals and direct radio communications between users and satellites (i.e., without using a ground station) led to the idea of using satellites in lower-altitude orbits than the geostationary orbit. Among possible orbit selections, low Earth orbit (LEO) satellites with altitudes between 500 and 1500 km and medium Earth orbit (MEO) satellites with altitudes between 5000 and 13000 km were considered (Jamalipour 1998). The altitude selection assures that the satellites reside outside the two Van Allen belts to avoid the radiation damage to electronic components installed in satellites. The use of these non-geostationary satellite orbit (NGSO) systems for commercial purposes started a new era in mobile satellite communications. Use of spot beam antennas in these satellites produces a cellular type structure within coverage areas; hence, a frequency reuse scheme could be applied, making the system a high-capacity, cellular-like network on the ground with satellites acting as the base stations in space.

NGSO satellite systems solved the problem of long propagation delay and high power consumption, but they introduced new challenges to the communications industry. Although it is possible to cover the world (excluding polar regions) with three GEO satellites, NGSO satellites

are closer to the Earth; thus, a constellation consisting of tens of satellites is required. This means increased system complexity and, of course, higher cost to the satellite system, which eventually must be passed to the users. Many NGSO satellite systems were proposed in the early 1990s in North America and around the world and obtained frequency spectrum licenses. Only a few of these systems were completed and became operational, including IRIDIUM (1998) with sixty-six satellites and GLOBALSTAR (2000) with forty-eight satellites. However, financial problems associated with the high cost of LEO systems forced both systems to file for bankruptcy. Consequently, LEO satellite systems have changed their goal of ubiquitous market penetration and services, and continue to serve for various specialized applications such as defense and emergency. Beside higher network complexity and more expensive control management requirements of NGSO satellite systems, a LEO or MEO satellite generally has a shorter lifetime than those in geostationary systems. This results in more frequent satellite launch requirements and higher maintenance costs to the satellite system.

The financial failure of the advanced but complex IRIDIUM satellite system revealed that although the technology for implementing a mobile satellite phone system is available, it is not possible with the system then designed to compete with the fast-growing terrestrial cellular systems and new Internet services using LEO satellites. The roaming capabilities between 2G networks in different countries and those considered in 3G wireless networks are quite adequate to provide telecommunications services to the majority of the world population at lower cost and better quality (e.g., lower delay) than those that can be achieved through such satellite systems. The new trends in the telecommunications industry with regard to transmitting data and Internet traffic at high speed over wireless channels could not be matched by these satellite systems. The IRIDIUM system, for example, was able to provide short data services at the very low data rate of 2.4 kbps. However, later systems such as the geomobile THURAYA have had better success.

Satellite systems do, however, maintain their unique feature of broadcasting. *Satellite broadcasting* has been successful for a long time and continues its dominance for long-distance coverage and service to highly populated areas. Broadband satellite systems are now being incorporated into the new trends in the telecommunications industry toward high-speed Internet access.

Broadband satellites are systems that can provide high data-rate transmission in the order of one Mbps and above (Jamalipour 2001). Digital video broadcasting (DVB) systems such as Eutelsat, SES, and INTELSAT; proprietary systems such as Spaceway and iPSTAR; and proposed but undeployed systems such as Teledesic and Astrolink are among such broadband satellite systems. Standardizations of these satellite systems are ongoing to reduce cost, increase applicability, and support multicasting. GEO satellite systems are of significant interest to these services. Figure 1 depicts a simple architecture for supporting high-speed Internet access. Recently, uplink over satellite has become the preferred architecture as opposed to uplink through terrestrial link via dialup (illustrated as the dashed connection to the dialup server in Figure 1).

Broadband satellite systems can be categorized according to their specifications and capabilities. This could be based on the frequency bands of operation (C band 4–8 GHz, K_u band 10–18 GHz, K_a band 22.5–40 GHz, and higher bands Q/V 37–100 GHz), the orbit altitude and hence the satellite lifetime, power requirements and antenna size, usage of bent pipe or on-board processing (OBP) technologies, global or regional coverage of the system, satellite total capacity and user capacity, use of inter-satellite links (ISL), number of supported terminals and required gateways, protocol used in the satellite system (e.g., TCP/IP, DVB, ATM, etc.), use of open or proprietary standards, total number of satellites in the system, and total cost. Most new designs of satellite systems include OBP and on-board switching (OBS) facilities so that the satellite node changes its simple role of relaying into being an active element in the network. OBP is a general term that refers to signal

Figure 1: An architecture for satellite high-speed Internet access

processing and routing functions implemented on-board the satellite that go beyond the amplification and frequency conversion performed in conventional, transparent satellite systems. Switches in the satellites provide short latency and thus improve the QoS with regard to systems using hub stations on the ground. By using a sophisticated constellation with ISLs, connectivity in space without any terrestrial resource is possible. This feature enables far more autonomous satellite networks, which may be imperative especially for military purposes and post-disaster communications situations, where ground facilities may become potential targets or be damaged. These benefits, however, demand payloads with higher complexity.

There are many regulatory and standard bodies currently involved in development of issues related to the satellite communications industry. Regulatory bodies include the World Radio Conference (WRC), the Federal Communications Commission (FCC), the International Telecommunications Union (ITU), the European Radiocommunications Office (ERO), and many national and regional regulatory organizations. Standards are mainly developed by the Internet Engineering Task Force (IETF), the European Telecommunications Standards Institute (ETSI), the Telecommunications Industry Association (TIA), and the ITU.

Satellite systems have longer development cycles compared to terrestrial systems, and less funding and fewer engineers are usually involved in their development. Moreover, they compete over a more limited market than cellular systems. Most satellite systems are still proprietary and interfaces are not public, which in turn prevents competition. The standards for satellites will ensure interoperability and real competition and will be required for a broader consumer market. Therefore, in order to see further development in broadband satellite systems, a widely acceptable standardization is vital.

SATELLITE IP NETWORKING

Satellites in IP Networks

New multimedia and Internet services demand more cost-effective, high-quality, and high-speed telecommunications technologies and architectures. The primary issue is how to expand the current global Internet infrastructure so that the QoS can be improved from current best-effort service so that high-speed access can be economically provided. In this context, satellites can play an important role in expanding the Internet infrastructure using the large coverage area feature and providing high-speed data transmission through a high-bandwidth capacity channel. Satellites, however, would not perform this task as an isolated network but rather use an efficient integration with current terrestrial networks. So, instead of having an IP network in the sky, as suggested in earlier proposals on some satellite IP networks, a combination of terrestrial and satellite networks would be a solution to the future high-speed Internet (Marchese and Jamalipour 2005).

In a global Internet infrastructure, satellites can be used for many purposes. They can be used to connect geographically distant segments of the network or to interconnect heterogeneous networks. Satellites can provide

direct telecommunications service to aircraft, ships, fast trains, and isolated local networks on the ground, or even to individual users. Flexible and quick deployment of bandwidth by satellite systems make them easily approachable by densely wired networks when required, as a good backup and support network.

Figure 2 shows two different options for the satellite payload that can be used in satellite-based Internet architectures. In Figure 2(a), the satellite is used as a reflector in space connecting separate network segments through ground gateways. In Figure 2(b), however, the satellite acts as an active component of the network that can utilize routing and switching processing. The satellites used in Figure 2 can be on any of the altitudes explained earlier—GEO, NGSO, or a combination of different altitudes. The satellites shown in Figure 2(b), in addition to having connection to the ground gateways, are also employed in intersatellite links so that network connectivity can be created in space independently. This method should be considered an important option in a future satellite-based Internet architecture. The method requires higher costs for the system and more complicated routing management. If special facilities are included in the mobile stations on the Earth, both methods can provide direct Internet connectivity to remote users without any other alternative terrestrial telecommunications infrastructure. A summary of this satellite-based Internet architecture and current proposals of this kind can be found in Kota, Pahlavan, and Leppanen 2003, and Marchese and Jamalipour 2005; Hu and Li 2001.

A satellite node can also be used as a high-speed downlink for home Internet access. Using this method, a home or office user with a satellite receiver, usually used for satellite television, can download the Internet contents at a very high data rate through the satellite downlink channel. A simple architecture of such a satellite-ground high-speed Internet was shown in Figure 1. In the architecture shown in this figure, the user first connects to his or her Internet service provider (ISP) using a normal dialup connection. The dialup connection forms a low-speed data communication (e.g., a usual 56 kbps or integrated services digital network [ISDN] connection) mainly in order to send requests to the Internet servers at the local ISP site. All Internet contents can then be forwarded to the customer through the high-speed satellite downlink upon receiving the request. The downlink can send the data to the user at speeds of one to a few Mbps using DVB satellites or other types of satellites. This method is especially appropriate for video-on-demand and real-time Internet applications in which many users located in the same region want to retrieve the same contents over the Internet. The asymmetry in the Internet traffic that usually results in up to ten times more data traffic on a typical Internet downlink connection compared to the uplink makes this method of special interest and application. Currently this method is competing with other high-speed Internet access for home users including cable modems and asymmetric digital subscriber line (ADSL) technologies. Some prototypes of these satellite Internet systems for home users have been already developed and demonstrated in Europe and other parts of the world. With some modifications addressing mobility and safety, it is possible to

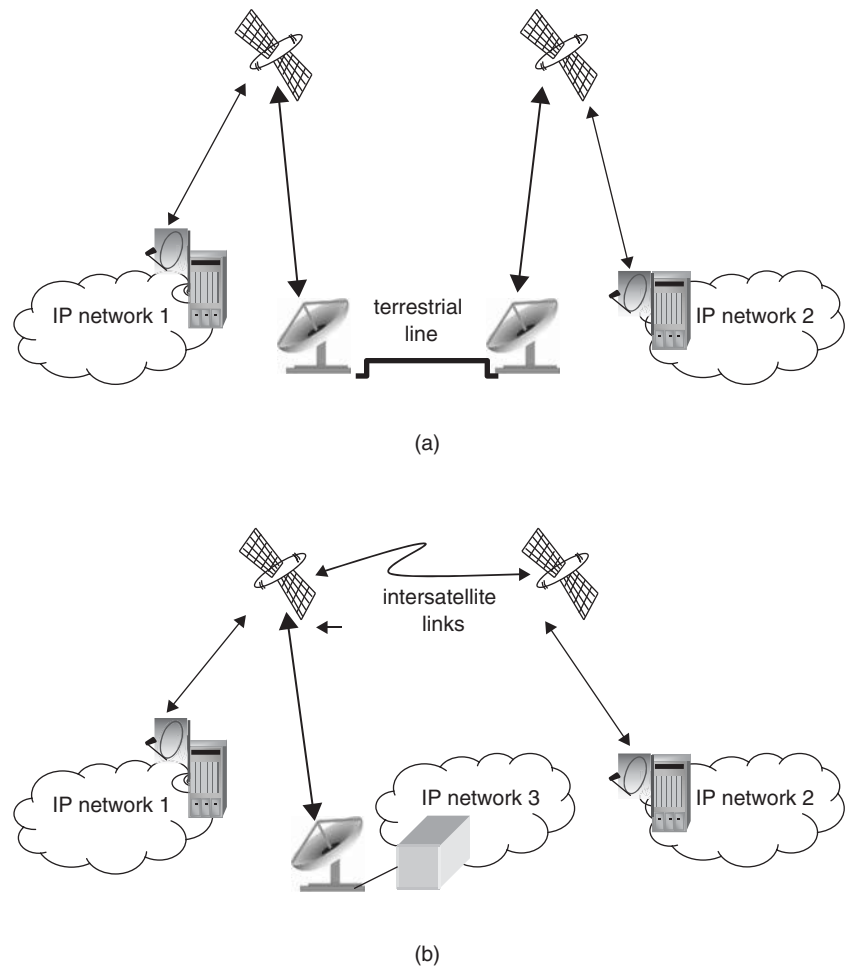

Figure 2: Two different payload options for satellite-based IP architectures: (a) bent-pipe architecture and (b) on-board processing satellites

extend the coverage of this type of Internet access to mobile users on the ground and also to long-distance flights and ships. For instance, Connexion service by Boeing began delivering real-time, high-speed Internet connectivity to airline passengers in 2004.

Satellites in 3G and B3G Networks

With the increasing popularity of portable computers and the expanding Internet capabilities of mobile phone handsets, a large demand for mobile computing has been generated in the past few years. Thus, instead of restricting data connections to be maintained always at a fixed position in the network, mobile users will be provided with equivalent multimedia and IP services. There is no doubt that the trend is toward a global mobile networking environment. In such a network, broadband satellites can be considered an integral part of the network, interconnecting the fast-growing terrestrial cellular and wired networks (Marchese and Jamalipour 2005).

Broadband satellite networks for Internet access are the new generation of satellite networks in which Internet-based applications and services will be provided to users regardless of their degree of geographical mobility. Asynchronous transfer mode (ATM) is a potential candidate for the switching mode for future broadband satellites due to its support of a variety of traffic, such

as constant and variable bit rate and QoS support (Jamalipour 1998). Nevertheless, IP routing is considered the primary alternative for these satellites due to lower cost and friendliness to Internet traffic.

In the sphere of terrestrial networks, there are at present two possible approaches for establishing the task of mobile computing: cellular-based and IP-based solutions (Jamalipour 2001; Marchese and Jamalipour 2005). Intuitively, whereas a cellular-based solution enhances the current mobile communications by extending capacity for data and multimedia transmissions, an IP-based solution allows for user mobility by maintaining all ongoing Internet connections even in the presence of frequent handoffs or changes in the network points of attachment. In the forefront of these technologies, 3G and B3G wireless systems are being considered. These systems evolved by orienting the integration of three essential domains: broadband, mobile, and Internet. In such a milieu, the increasing feasibility of virtual connections allows mobile users not only to roam freely between heterogeneous networks but to remain engaged in various forms of multimedia communications. Whether this involves geographical coverage, bandwidth, or delay, it would then be up to the users to decide when and how to switch from one access network to another depending upon the availability and appropriate cost/performance considerations, advancing toward an era of all-IP based communications.

Consequently, it will be necessary to implement the 3G system as a universal solution that prompts transparent user roaming (among different wireless networks) while delivering the widest possible range of cost-effective services.

International Mobile Telecommunications-2000 (IMT-2000) is a unified 3G mobile system that supports both packet-switched and circuit-switched data transmissions with high spectrum efficiency, making the vision of anywhere, anytime communications a reality. Basically, this is a collection of standards that provides direct mobile access to a range of fixed and wireless networks. The three most significant developments are universal mobile telecommunications system (UMTS), code division multiple access 2000 (CDMA2000), and universal wireless communication-136 (UWC-136), which are the 3G successors to the main 2G technologies of global system for mobile communications (GSM), interim standard 95 (IS-95), and advanced mobile phone service (AMPS), respectively (Steele, Lee, and Gould 2001). The general idea was to make the development of 3G wireless technologies a gradual process from circuit-switched to packet-switched. Take GSM, for example: in order to have the system enhanced with improved services (by means of increased capacity, coverage, quality, and data rates), the evolution to 3G was made possible through the incorporation of an intermediate stage called general packet radio services (GPRS).

Based on the enhanced core network of GPRS, UMTS is designed to be the backward-compatible 3G standard for GSM. UMTS is the European proposal for a 3G mobile system aiming to support multimedia services with extended intelligent network features and functions. As a first step of the integration, the UMTS terrestrial radio access network (UTRAN) will coexist with GSM access networks. The idea was to develop the UMTS core network by gradually incorporating the desired UMTS features to the GSM/GPRS core network. At this stage, UTRA supports time-division duplex (WCDMA-DS TDD) and frequency division duplex (WCDMA-DS FDD) modes with the combined operation offering an optimized solution to coverage areas of all sizes. A further multi-carrier (MC-FDD) mode is to be established at a later date intended mainly for

the use in CDMAOne/CDMA2000 evolutions (Steele, Lee and Gould 2001).

For satellite systems, the situation is different. The most apparent variation is that the market for satellite systems is much more limited than for their cellular counterparts. Therefore, it would be difficult to assume the same approaches for satellite systems. Instead, satellite systems can incorporate their global coverage feature for enhancement of the 3G terrestrial networks. Satellites can establish a high-speed backbone network to support the terrestrial networks and also to use their broadcast nature to deliver Internet content at high speeds directly to a group of users.

Satellite UMTS (S-UMTS), for example, is considered as a component of 3G networks (Priscoli 1999). The satellite segment of the network connects through appropriate interworking units (IWU) to the ground segments. IWU for the satellite has similar functionality as the gateways used to interconnect 2G and 3G networks for interoperation of these networks during the transition period from 2G to 3G, as well as the gateways used for interconnection of different operator networks of the same kind (e.g., GSM). For example, Figure 3 illustrates a new hybrid architecture consisting of a GEO satellite and some terrestrial 3G segments that is proposed as part of a European Satellite Communications Network of Excellence (SATNEX) project (Giambene 2005). A service center acquires information from diverse content providers on the Internet. The server distributes contents in regional caches. From local caches, information is sent to mobile users through GEO bent-pipe satellite links. Upstream transmissions from the Earth station to the MT employ a DVB-S-like air interface operated in K_u band. Downstream transmissions (acknowledgment packet [ACK] of layer 2 and layer 4) from mobile terminals move through a 3G terrestrial cellular system. The terrestrial return channel provides adequate capacity for small ACK packets, requires low transmission power, and allows for the reduction of round trip time (RTT) values.

Another similar integrated approach is hybrid terrestrial/satellite broadband services based on the ancillary terrestrial component (ATC). These hybrid services use a ground tower network of ATCs operating in L band

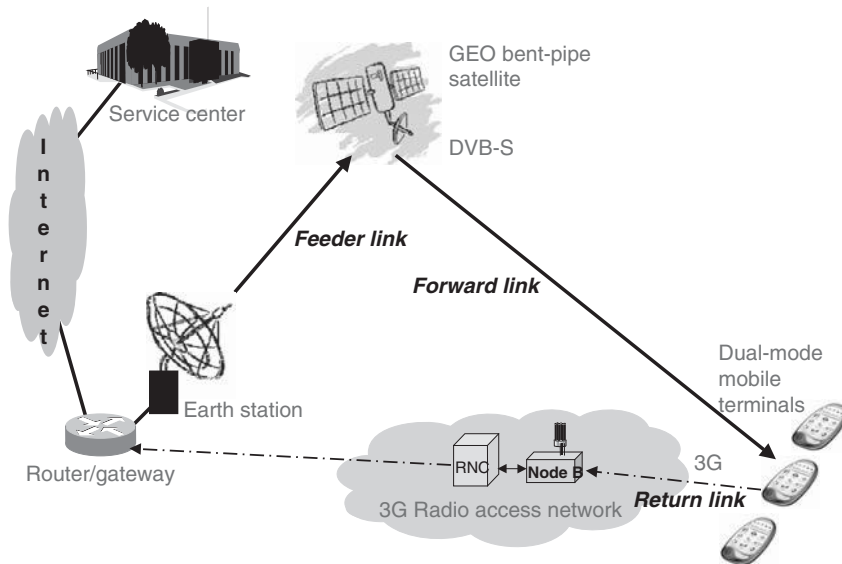

Figure 3: A hybrid architecture consisting of GEO satellites and terrestrial 3G segments

to boost the signal in dense urban environments, eliminating signal fading and interference issues common to all-satellite, first-generation MSS networks. The ATC approach was introduced into the MSS world in 2001 when the FCC authorized its use on a new system to be built by U.S.-Canadian operator Mobile Satellite Ventures. ATC supports seamless availability of service within an entire region, and the infrastructure for this MSS/ATC network can be acquired from wireless vendors using 3G/4G configurations. This allows ATC operators to offer low-cost user devices, as in the case of terrestrial operators. Moreover, with the use of L band by ATCs, the same spectrum operating over the satellite can be reused terrestrially.

Multilayered Satellites in IP Networks

Multilayered satellite architectures with interorbital links (IOLs) between layers of satellite constellations are of much interest because they may yield better performance

than individual layers. Figure 4 depicts a layered satellite architecture with some Internet-based applications. For example, Dash, Durresi, and Jain (2003) consider a three-layered architecture consisting of GEOs, LEOs, and high-altitude platforms (HAPs) for VoIP application. GEOs act as backbone routers, LEOs as the second layer, and HAPs to cover special areas with high and sensitive traffic, such as battlefields and disaster areas.

CHALLENGES FOR SATELLITES IN IP NETWORKS

In this section we look at some challenging issues with regard to supporting satellite IP networks.

Physical Layer Challenges

Satellite IP networks require advanced communications technologies to increase link capacity and utilize

Figure 4: Layered satellite architecture with some applications

power performance and bandwidth efficiency. To achieve these aims, research on multiple fronts is under way at the physical layer. The research includes, but is not limited to, adaptive and higher-order modulation, adaptive coding, link budget analysis, adaptive power control, channel modeling, and integrated access control mechanisms. For example, instead of conventionally used quadrature phase shift keying (QPSK) modulation, 8-PSK or 16-quadrature amplitude modulation (QAM) are shown to be more efficient. Another example of research results at the physical layer is the standardization Turbo code for DVB-RCS. Although this section will not describe all of these topics, we will provide some important challenges at the physical layer for satellite IP networks. Figure 5 shows the architecture of a satellite IP network with return channel systems subject to channel problems. As seen in Figure 5, the following three system architectures for multimedia satellite networks may be distinguished: one-way communication, two-way communication with telephony return channel, and two-way communication with a transmitter at the user location. The last architecture includes different options: return link via a high-speed GEO satellite, or a lower-speed MEO or LEO (Alagöz et al. 2004). Moreover, in multimedia satellite networks, a return link may follow Link 1, Link 2, and Link 3 in Figure 5. Although any backhaul network would work, the LEO constellation enables the user to set up a GEO digital field terminal (DFT)—in which there is no terrestrial backhaul—and have immediate interconnection to a remote backhaul network. For example, a

control mechanism system may be utilized to handle the physical channel problems (Alagöz et al. 2004).

Performance over satellite channels may suffer because of the variation in the channel quality due to fading, propagation anomalies, jamming, and so forth. As a consequence of these variations, the channel bit error rate may range from having almost no impact on performance to dramatically degrading performance depending on the channel conditions. Among the channel error recovery techniques used in wireless environments are automatic repeat request (ARQ) and forward error correction (FEC) techniques, or their combinations. However, in a satellite application, the ARQ techniques may not be suitable due to latency constraints, especially for real-time applications. On the other hand, there is a trade-off when employing the FEC mechanism; although the FEC may enable the system to recover erroneous packets in adverse channel conditions, processing delay due to the FEC overhead may cause further congestion and more packet loss in the network (Alagöz et al. 2004). Satellite extension of terrestrial networks is a viable capacity and coverage improvement solution. Extensive works are also being carried out in terrestrial- and satellite-UMTS (T/SUMTS) interworking. T-UMTS applies a well-configured wideband code division multiple access (W-CDMA) air interface described by 3rd-Generation Partnership Project (3GPP) standards, whereas the S-UMTS radio access network is still under standardization. The main concept of T/S-UMTS interworking is to employ the same air interface requiring only minor modifications of the terminals and aided with adaptive radio resource management (Karaliopoulos et al. 2004).

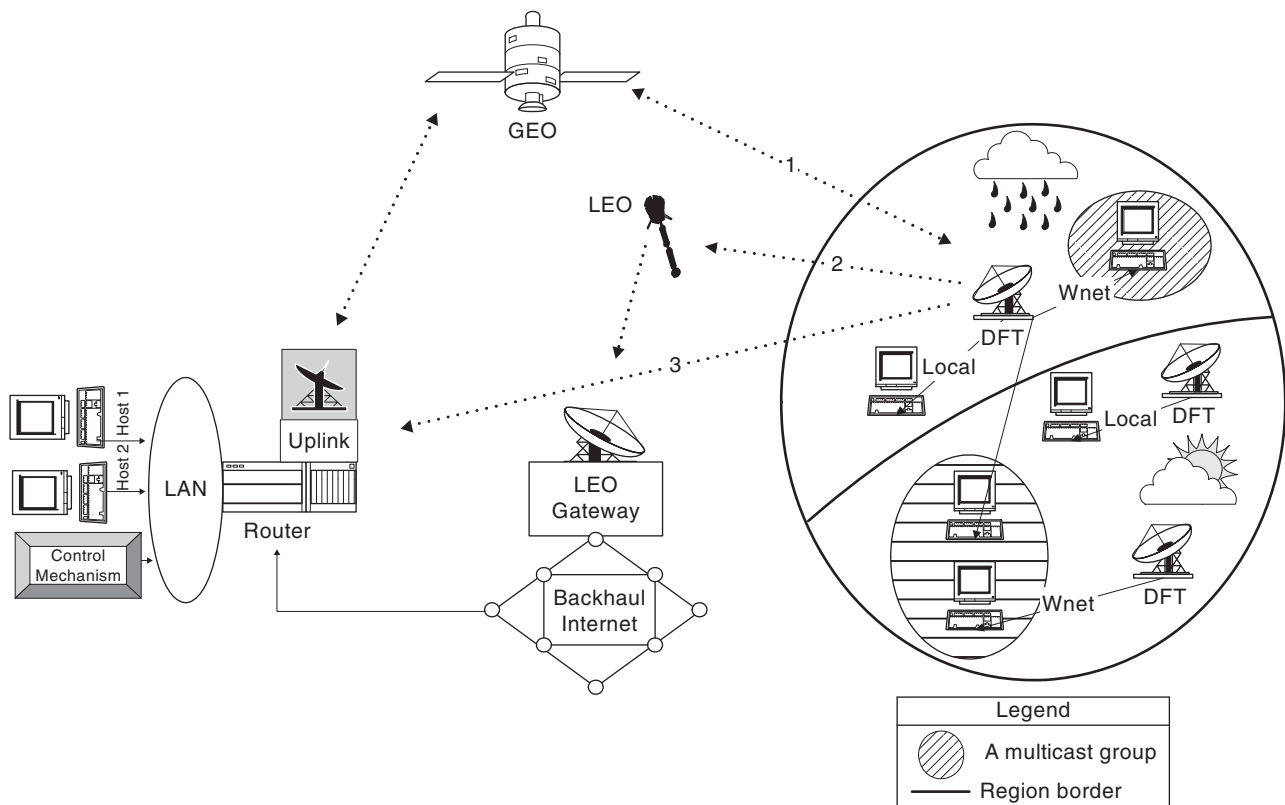

Figure 5: Architecture of a satellite IP network with return channel systems faced with channel problems

Through the use of communication satellites, networks can be interconnected on a global scale, even in geographic regions with poor terrestrial backbone infrastructure. As for the transport of data over satellite networks, protocol stacks can be optimized for the given physical characteristics. However, as IP has become the dominant networking protocol, satellite-dependent protocols have been reduced to physical layer and medium access control (MAC). The resulting protocol stack is summarized by the ETSI broadband satellite multimedia (BSM) scheme (ETSI-TR-985 2002). That scheme has been presented by the satellite standardization community as the reference architecture that allows IP over satellite. A special function is under investigation for allowing the interworking of TCP/IP protocol and satellite MAC. Matching the applications that use TCP/IP with the advantages offered by satellites, it is natural to think of TCP/IP-based applications over satellite networks; however, the general characteristics (e.g., fading) of the links heavily affect the performance of the communication (Bisio and Marchese 2004).

Medium Access Control

Recently many MAC protocols have been proposed for supporting link layer attributes of satellite networks with different user requirements and channel characteristics (Marchese and Jamalipour 2005; Barsocchi et al. 2005). Fundamental issues in designing multiple-access schemes are also summarized for next-generation mobile networks (Jamalipour, Wada, and Yamazato 2005). MAC protocols may be classified based on their functionality and characteristics as fixed assignment (FAMA), random access, demand assignment (DAMA), reservation, adaptive, and hybrid combination protocols.

In FAMA protocols, MAC can be employed to control user access to a shared satellite channel based on frequency division (FDMA), time division (TDMA) or code division (CDMA). Unfortunately, for FAMA-based protocols, the inherent nature of traffic burstiness in satellite channels may cause inefficient utilization of channel resources. Both TDMA- and CDMA-based return channel protocols are also under investigation for DVB-RCS systems. In random access protocols, users access the channel in an uncontrolled and uncoordinated fashion. Unfortunately, the resulting collisions can be minimized only at the expense of low utilization and throughput. This scheme maybe used in bursty traffic conditions with non-guaranteed successful transmission. In order to improve the performance of conventional random access techniques, other techniques including pure ALOHA, slotted ALOHA, selective reject ALOHA, capture ALOHA, adaptive spread ALOHA, and more were proposed. ALOHA was one of the first protocols introduced for packet satellite networks with throughput of 18 percent. Subsequently, slotted ALOHA and contention-resolution-based ALOHA variants were proposed, achieving throughputs of 37 percent and 43 percent, respectively (Kota, Pahlavan, and Leppanen 2003). Although random access may support larger number of terminals with bursty traffic, QoS is not guaranteed. The demand assignment multiple access (DAMA) technique addresses this issue, utilizing dynamic allocation

of the system bandwidth in response to users' bandwidth requests. A resource request must be granted (reserved), given that a certain level of QoS will be maintained during transmission. DAMA-based protocols include reservation ALOHA, priority-oriented demand assignment (PODA), fixed priority-oriented demand assignment (FPODA), and round-robin reservation techniques, combined free demand assignment multiple access (CFDAMA). For example, CFDAMA may support different QoS requirements for bursty traffic (Mitchell 2003). Some of their extensions and hybrid combinations are also adopted for satellite networks. These include predictive DAMA (PRDAMA), bursty targeted DAMA (BTDAMA), combined random/reservation multiple access (CRRMA), transmit before assignment using collision request (TBACR), movable boundary random/DAMA, and a few other protocols along with their performance analysis in satellite networks as given in Mitchell (2003). Unfortunately, there is no unified protocol that is superior to others for different traffic scenarios and applications. Some protocols with certain characteristics may be more suitable for particular satellite networks. The fact is that large bursts require extra buffers and higher processing capabilities to support reliable communications and guaranteed QoS. Both FAMA and DAMA are inefficient for bursty traffic. At the expense of increased design complexities, dynamic allocation strategies with random/reservation algorithms may be used to improve the throughput while keeping the delay parameters random but at an acceptable level.

Integrated layered approaches are needed to increase performance of MAC protocols. For example, with regard to physical layer attributes, TCP and/or application-layer characteristics may have a potential impact on the performance of a MAC protocol. Consider that TCP incorporates a window-based flow control algorithm with an associated TCP window size (W) control. If TCP enters congestion avoidance, W will be reduced significantly and will start a slow incremental process based on successful ACKs. That is, TCP will have the flow control of packets across a network from end-to-end and will change the packet arrival process at the satellite access point from that of an uncontrolled source (Mitchell 2003). In addition, traffic burstiness is an important characteristic that strongly influences the design or selection of a MAC protocol for satellite networks. Unfortunately, comparative studies in the literature are based on a few limited-arrival distributions with limited burst nature and message length distribution. This problem should be clarified as part of the sensitivity analysis of designed protocols.

Mobility and Handover Management

Due to higher-speed movement, the mobility management in LEO systems is more challenging than in MEO systems. Clearly, mobility is managed largely through the process of location management. In this section, we describe handover types in LEO satellite networks and location management issues.

Link Layer Handover

Inter-satellite handover occurs when the end user's communication point is changed from one satellite to another.

The research in this area focuses on algorithms for the dynamic rerouting of a connection and the admission control of handover calls to ensure QoS requirements, because the change of satellite will affect the routing of the ongoing session and the resource allocation of the satellites. The spot beam handover occurs when the mobile user switches between the spot beams of a satellite. Spot beam handovers occur very frequently (e.g., every one to two minutes) due to the small coverage area of a specific spot beam. Admission control algorithms and schemes for reducing the blocking rate for handover connection and new connections is the main concern of the research conducted in this area (Cho et al. 2002). Link handover may occur when a satellite passes over the polar area. The aim in this handover type is to reduce the signaling overhead and blocking probability caused by link handovers. Link layer handovers cause the change of one or more links between the two communicating end points. Link layer handovers may result in a change of the IP address for the end points in such a way that a network layer handover is required after a link layer handover.

Network Layer Handover

If either satellite or user terminal changes its IP address due to the movement of the satellite or the mobile user, a network layer handover is required to transfer the connection of higher-level protocol (e.g., TCP, UDP) to the new IP address. Two events that cause network layer handover in a satellite environment can be defined as follows.

Satellite as a router: When a satellite is used only for routing and does not generate or consume data, the satellite acts as a router to the Internet. Mobile users are handed over from one satellite's footprint to another as they come under the footprint of different satellites going around the earth. The mobile node (MN) needs to maintain a continuous transport layer connection with the correspondent node (CN) while their attachment point changes from satellite A to satellite B. Different satellites or even different spot beams within a satellite may be assigned different IP network addresses (Tuysuz and Alagöz 2006). Therefore, IP address changes that occur during an inter-satellite handover require a network layer handover. Routing management will be described later in the chapter.

Satellite as a mobile host: When a satellite has on-board equipment to generate data that are transmitted to workstations on the earth, or it receives control signals from the control center, the satellite acts as the end point of the communication. Although the satellite's footprint moves from ground station A to B, the satellite should maintain continuous transport layer connection with its CN. If the IP address of the satellite has to be changed when it is handed over to ground station B, a network layer handover has to be performed.

Mobile IP (MIP) is the standard proposed by the IETF to handle mobility of Internet hosts for mobile data communications. Some projects conducted by the National Aeronautics and Space Administration (NASA) consider IP in satellite networks and Mobile IP. Some of these

projects also involve handovers in satellite networks. Such projects include the Operating Missions as Nodes on the Internet (OMNI) project and the Global Participations Measurement (GPM) project (Rash, Casasanta, and Hogie 2002). In addition, an analytic study of Doppler-based handover management for LEO satellites is provided in (Papapetrou and Pavlidou 2005).

Location Management

Obviously, mobility is managed largely through the process of location management. This action involves not only storing and/or retrieving information from the location database but sending paging signals whenever necessary to locate a roaming user. Although the need to notify the home network of mobile users' current locations is always present, it is questionable whether accurate location information is essential for mobile nodes that are not committed to any data transmissions. New research results for location management are crucial for improving the overall performance of satellite networks.

Mobility Management in Mobile Satellites

Mobile satellite systems using NGSO have very similar characteristics to cellular networks; thus, issues are common between these networks. The main similarity is that most of these systems use the cellular concept of increasing the total system capacity through a cellular-like coverage area arrangement, introducing similar handoff issues to those involved in cellular systems. There is, however, a major difference between the proposed scheme in satellite systems and what exists in the sphere of cellular networks. The key operational concept that differentiates the specific operations of mobility management in the two systems is the "entity" being considered as the moving object. Whereas the former encounters *mobile* movements within the fixed network architecture, the latter incurs *satellite* movements in reference to fixed mobile nodes. Essentially, this suggests that the mobility management technique will be different.

It is crucial to more closely identify the differences (or similarities) between the operations of handoff and location management in mobile satellites. Clearly, handoff management is significant only when the mobile is active; specifically, it is about the appropriate reservation of resources (e.g., bandwidth) along the roaming path of a mobile user engaging in a call connection. Its efficient operation is important to ensure that the various aspects of the QoS requirements (e.g., throughput versus forced call termination) are satisfactorily complied with. Location management, on the other hand, is mainly for users who are currently idle but are expected to receive calls (or become active) while they frequently change their point of attachment to the network. In essence, only sufficient location information (about the mobile) is maintained so that the network can loosely track the mobile's movement and subsequently incur a minimal paging (or searching) load when the precise residency is required. Consequently, it would be correct to conclude that the predicted information for handoff needs to be more reliable than the information desired for efficient location management. Based on this observation, it seems potentially viable to

combine (at least to some extent) the operations of the two management processes of handoff and location.

Routing Management

In the context of NGSO systems with ISLs, one of the major challenges is employing an efficient routing protocol that yields effective use of satellites and ISLs to improve the performance of the satellite system. Specifically, due to dynamic topology with respect to satellite movement, it is hard to adopt well-known terrestrial, connection-oriented IP routing protocols like open shortest path first (OSPF) and routing information protocol (RIP) to satellites. These protocols rely on the exchange of topology information, which quickly becomes obsolete and must constantly be refreshed with new information. However, although topology of a satellite network rapidly changes, it is periodic and predictable because of the strict orbital movements of satellites. Therefore, it is reasonable to use this periodicity feature when calculating routes.

Dynamic virtual topology routing (DVTR) and virtual node (VN) protocols are common routing methods that use the periodicity of the topology changes (Werner 1997). DVTR divides the system period into a set of time intervals, so that topology remains constant during each interval. Time intervals are chosen to be short enough to assume that the traversal costs of ISLs are fixed. Therefore, optimal and alternate paths can be established using a shortest path algorithm (Werner 1997). The DVTR approach decreases the online computational complexity but adds the expense of large storage requirements. Using the VN technique, a fixed virtual topology consisting of virtual nodes is superimposed over the physical topology in order to hide the mobility of satellites from routing protocols. Each satellite corresponds to a VN at any given time. As a satellite disappears over the horizon, its corresponding VN becomes represented by the next satellite passing overhead, and the state information (such as routing table entries) is transferred to it. Routing is performed in the fixed virtual topology by the use of a common routing protocol. This scheme can directly integrate the space network with the terrestrial IP network and may provide good support for IP-multicast and IP-QoS. However, this approach has some challenging problems such as scalability of routing tables and high computational complexity in space devices.

In a satellite network, routing decisions can be made offline or on-board. In the former case, the routing algorithm could use information about predictable topology changes (e.g., changes in the ISL lengths and connections), but it would not be adaptive to traffic load changes. Therefore, on-board routing algorithms yield better efficiency for dynamic traffic cases at the expense of increased complexity.

There are various adaptive routing protocols that take the traffic characteristics into account. In the simpler case, the routing protocol is isolated, which means it uses only the information (e.g., outgoing link loads) local to the node where the routing is performed. Priority-based adaptive routing (PAR; Korçak and Alagöz 2005) is an example of isolated adaptive routing algorithms, in which each ISL is assigned a priority depending on its past utilization and

buffering information. When selecting an outgoing link among reasonable ones, the priorities may be utilized to evenly distribute the traffic. Non-isolated adaptive routing algorithms, on the other hand, take into account all the other nodes and ISLs in the network. These algorithms rely on a signaling protocol in order to transport state information between nodes in the network. Therefore, non-isolated algorithms may cause high signaling overhead, as well as additional complexity in the satellite nodes (Korçak and Alagöz 2005).

Some routing protocols are designed for layered satellite architectures. For example, in the satellite grouping and routing protocol (SGRP), LEO satellites are divided into groups according to the footprint area of the MEO satellites (Chen and Ekici 2005). Each LEO group is managed by a MEO. Depending on the state information arriving from the LEOs, a MEO satellite computes the minimum delay paths for its LEO members. The hierarchical approach aims to reduce computational complexity on satellites and the communication load on the network compared with the non-isolated algorithms.

IP Multicast over Satellites

Because of the nature of satellite broadcasting capability, IP multicast over satellites may need special treatment, especially for maintaining QoS and security constraints. Traditionally, multicast allows significantly reduced load at the transport network by a source node to send data simultaneously to all the intended multicast members. In order to employ a successful and reliable multicast IP over satellites, the design requirements include efficient link utilization, dynamic joining and leaving of a multicast group, minimal overhead, high return channel link, and security issues. For example, Sun et al. (2003) emphasize some modifications required for multicast networking protocols (e.g., Internet group management protocol [IGMP], multicast routing, reliable multicast protocols, and required security issues). A satellite network architecture is also presented in Ronga et al. (2003) to provide QoS support for IP traffic based on the DiffServ paradigm, while minimizing the satellite resource waste. The performance has been evaluated in terms of throughput, packet jitter, TCP protection against UDP flooding, and wasted bandwidth on the satellite link. Finally, while the tailoring of terrestrial multicast routing protocols are in progress for satellites, IP multicast over satellites may need further investigations for dedicated routing protocols—especially for channels subject to fading.

VoIP over Satellites

VoIP services have become popular in the last decade because of their low cost and simultaneous voice-data transmission in a single session. The use of satellites with OBP capabilities for voice communication can increase if the parameters leading to the targeted performance are carefully designed. A satellite with OBP can process the received data and, according to the nature of the application, decide on the transmission properties. VoIP performance issues in layered satellite networks with on-board processing capabilities are also under investigation. Performance is an important issue of a system that

results in the system being accepted by users or ignored. Therefore, parameters affecting the performance should be clearly stated (Nguyen et al. 2001). Users expect service quality from VoIP services similar to that of PSTN, which is a dedicated system for voice communication. Thus, the service levels that they face usually do not meet the expected service quality. Since voice applications are real-time applications; delay and delay variation are key parameters for the system performance. To achieve intelligible communication, delay must be restricted to certain values specified by the authorities (e.g., ITU and ETSI). Obviously, the significance of delay becomes more apparent for satellite networks. OBP with physical, data-link, and network layer functionalities may improve the performance of the application and ensure the desired quality. Satellites can buffer the incoming voice data and drop the damaged packets. Packet loss rate due to corruption and dropping, along with throughput values, show the efficiency of the system beyond delay and jitter, link utilization rate, or bandwidth efficiency.

Data and voice transmission over packet-based networks feature a major difference in requirements: data are loss sensitive and delay tolerant, whereas voice is loss tolerant and delay sensitive. For this reason, the transport layer in the VoIP protocol stack uses the user datagram protocol (UDP) to carry voice instead of the transmission control protocol (TCP). In addition, since most VoIP applications are real-time, the real-time transport protocol (RTP) is run on top of UDP to ensure end-to-end delivery services. These services include payload type identification, sequence numbering, time stamping, and delivery monitoring. Many parameters affect users' perceptions of quality, such as speech coding, packetization efficiency, silence suppression, error-concealment methods, and jitter buffer implementation.

The choice of VoIP coder-decoder (codec) depends on the available bandwidth and desired speech quality. There are a number of widely used ITU G-series codec standards, including G.711, G.726, G.729 and G.729a. Current VoIP systems typically use G.729a, which encodes and compresses voice down to 8 kbps using the code-excited linear predictive (CELP) algorithm.

VoIP packets have a long packet header consisting of IP/UDP/RTP—each 20, 8, and 12 bytes long, respectively. Header compression is a way to decrease the packet overhead. Header information that does not change after connection setup is not sent, and voice data of two or more call channels are multiplexed in one IP packet with a sub-header identifying call channels. VoIP is inefficient for small voice packets, whereas large packets lead to longer delays and more packet errors. Silence suppression helps to save average bandwidth by eliminating silent periods of transmission. Finally, with more advanced and powerful integrated circuitry and microelectronics, OBP has been becoming more feasible and sensible, cost-wise. Thus, it has the potential to enable satellite networks to cope with the inherent propagation delay burden (Janssen et al. 2002), contribute to performance of VoIP applications over satellite networks (Dash, Duresi, and Jain 2003), and support ETSI standards for compliance/interoperability, such as VoIP over DVB-RCS with QoS and bandwidth on-demand algorithm described in Marchese and Jamalipour (2005).

Security Management

One of the most critical aspects of satellite IP networks is security management. Satellite security can be implemented in the network, transport, and application levels. At the physical layer, satellite operators support securing the network access via a smart card. DVB standards employ two levels of security: DVB common scrambling and user scrambling in forward and return channel. At the application layer, many application-specific security solutions exist. Our main concern in this subsection is exploring IP security (IPsec) for satellites.

There are two main groups of investigations for resolving the security problems in satellites: tailoring the existing security solutions for satellite IP networks and designing a new security solution dedicated to satellite IP networks. IP security includes authentication, integrity, confidentiality, and key management issues for satellite IP networks. The broadcast nature of satellite links makes eavesdropping much easier than any other service on the Internet. Additionally, satellite security services should maintain IP security even in the presence of intentional security attacks.

The IPsec mechanism includes an authentication header and an encapsulation security payload header. Satellite communication takes different approaches regarding the dynamics of the different topologies within the network. Implementing IPsec for satellites is a major challenge (Howarth et al. 2004), and the performance of satellite IP networks may be adversely affected by some security solutions. For example, as we will see later in the chapter, utilizing performance enhancing proxies (PEPs) reduces the latency problem, but it increases the security gap at the network layer. Unless modifications are made, end-to-end IPsec with PEP cannot be trusted. One promising modification may be to employ multilayer IPsec in which TCP headers are layer one and TCP payload makes up the other layer, such that the latter can be separately encrypted. Because PEP itself must be protected from denial-of-service type attacks, traditional IP solutions such as firewall protection should be considered as well. Various IPsec implementations for satellites remain a major challenge (Marchese and Jamalipour 2005).

SATELLITE TRANSPORT OF INTERNET TRAFFIC

Broadband satellite networks are being developed to transport high-speed multimedia and, in particular, Internet traffic through high-capacity satellite channels to network segments as well as to individual users. As in the case of any other wireless network designed to deliver Internet traffic, broadband satellite networks need to connect to the backbone-wired Internet on the ground. TCP is the most commonly used protocol at the transport layer of the network stack in the Internet, originally developed in wired networks with low bit error rate (BER) on the order of less than 10^{-8} . In this context, any wireless network with Internet service needs to be compatible with the protocol used in the wired network (i.e., mainly the TCP/IP protocol). There are, however, some design issues in the TCP/IP protocol that make it difficult to use it efficiently over wireless and satellite links. Recently, many research

activities have compared the performance of TCP in high-BER and high-latency channels and modification proposals to improve its performance in terrestrial and satellite wireless networks (Jamalipour 1998; Kota, Pahlavan, and Leppanen 2003; Marchese and Jamalipour 2005; Partridge and Shepard 1997; Henderson and Katz 1999; Hassan and Jain 2003).

TCP has been designed and tuned for networks in which segment losses and corruption of performance are mainly because of network congestion. This assumption might not be valid in many of the emerging networks, such as wireless networks. The flow control mechanism used in TCP is based on time-out and window-size adjustment, which can work with high utilization in wired networks with low BER on the order of 10^{-8} . However, when the wireless channel is used (partially or totally) as the physical layer with a BER as high as 10^{-3} , it may perform inefficiently. In the wireless channels, the main cause for packet loss is the high BER, not congestion as it is in wired networks. The low efficiency of the TCP in a wireless channel occurs because TCP misinterpreted that the packet loss that occurred because of the high error rate was a result of congestion. On the other hand, in high-latency networks such as satellite networks, adjustment of the window size could take a long time and reduce the system throughput.

TCP has the ability to probe the unused network bandwidth by a mechanism called *slow start* and also to back off the transmission rate upon detection of congestion through the *congestion avoidance* mechanism. The congestion control mechanism implemented by standard TCP is based upon a sliding window, which defines the number of packets injected in the network. At the connection start-up, TCP initializes a variable called congestion window (cwnd) to a value of one segment. This variable determines the transmission rate of TCP. The congestion control phase typically occurs after the slow start phase ends depending on the slow start phase threshold value. The window size is doubled for every round-trip period until a packet loss is experienced. At this time, the congestion avoidance phase is commenced, the window size is halved, and the lost packet is retransmitted. During this phase of TCP, the window size is increased only linearly by one segment at each round-trip period and might be halved again upon detection of another packet loss. If the retransmitted packet is lost, the time-out mechanism employed in TCP reduces the window size to one. Because all of these procedures are performed at periods equal to round-trip delay of the channel, the system throughput could be degraded significantly when high-latency channels such as geostationary satellites are involved. Therefore, the high-latency satellite channel combined with the slow increase of the TCP congestion window size results in underutilization of the high-capacity satellite channel.

A similar issue for TCP over satellite links is the natively large bandwidth-delay product. The bandwidth-delay product defines the maximum amount of data that can be in-flight (transmitted but not acknowledged) in a TCP connection. It represents the full utilization of that connection. In a connection that incorporates a satellite link, the main bottleneck in TCP performance is a result of the large delay-bandwidth product of the satellite link (Ehsan, Liu, and Ragland 2003). Over such a link, the normal TCP

window dynamics result in significantly increased latency before the channel is fully utilized. This problem cannot be effectively solved simply by improving the satellite channel quality, or by using large initial window size. A connection using the satellite link typically also has a terrestrial part; thus, using large window end-to-end could affect the performance and fairness of the terrestrial part of the connection.

Satellite-Related TCP Modifications and Mechanisms

Some modifications to the basic TCP can be made so that it can perform more efficiently in high-latency satellite networks with Internet services. Most of the protocols described below can be found in detail in Jamalipour (1998); Kota, Pahlavan, and Leppanen (2003); Marchese and Jamalipour (2005); Partridge and Shepard (1997); Henderson and Katz (1999); and Hassan and Jain (2003). In this subsection, we present a brief description of such modifications and related mechanisms.

TCP Vegas

TCP Vegas includes a modified retransmission strategy that is based on fine-grained measurements of the round-trip time (RTT) as well as new mechanisms for congestion detection during slow-start and congestion avoidance. TCP Vegas's congestion detection mechanism is proactive; that is, it tries to sense incipient congestion by observing changes in the throughput rate.

TCP New Reno

TCP Reno does not generally recover well in the presence of multiple segment losses within one window's-worth of data. Only the first loss segment is recovered via the fast retransmit algorithm, and the rest normally must wait for a retransmission time-out recovery (the fast recovery phase is terminated after the first retransmission is acknowledged). The TCP New Reno proposal modifies the fast retransmit/fast recovery algorithms of TCP Reno to allow recovery from multiple segment losses (RFC 2582).

TCP Selective ACK

TCP with selective acknowledgment has been proposed to efficiently recover from multiple segment losses (RFC 2018, 2883). In selective ACK (SACK) TCP, acknowledgments contain additional information about the segments that have been received by the destination. When the destination receives out-of-order segments, it sends ACKs (SACKs) acknowledging them.

TCP for Transactions

TCP for transactions (T/TCP) attempts to reduce the connection handshaking latency for most connections from one and a half to one RTT for small transactions (RFC 1644). After the first connection between a pair of hosts is established, T/TCP is able to bypass the three-way handshake, allowing the sender to transmit data in the first segment. This reduction in latency can be significant for short Web traffic over satellite links.

Explicit Congestion Notification

Explicit congestion notification (ECN) allows routers to inform TCP senders about imminent congestion without dropping segments (RFC 3168). The ECN mechanism can be used as part of a mechanism to differentiate between congestion and error losses in satellite networks. The implementation of ECN requires the deployment of active queue management such as random early detection (RED) in routers.

Window Scaling and Large Initial Window Size

Small window size can severely limit TCP throughput over long propagation links. With the window scaling option, the amount of data that can be outstanding is significantly increased by introducing a scale factor to be applied to the window field. Consequently, TCP over a satellite connection can theoretically achieve a throughput of 15 Gbps, which is more than adequate for current satellite IP networks (Kota, Pahlavan, and Leppanen 2003). However, increased window size can also cause sequence number wraparound problems for TCP. To address the wraparound problem, TCP needs to implement two mechanisms—namely, protection against wraparound sequence (PAWS) numbers and round-trip time measurements (RTTM).

Pacing TCP Segments

Rate-based pacing (RBP) is a technique used in the absence of incoming ACKs, in which the TCP sender temporarily paces TCP segments at a given rate until the ACK clock can be restarted. As soon as the first acknowledgment is received, RBP ceases and TCP ACK resumes. Pacing data during the RTT of transfer may allow TCP to make effective use of high bandwidth-delay pipes, such as satellite links, even for the short transfer.

Header Compression

Header compression is a general bandwidth-efficiency technique and is also applicable in satellite IP networks (RFC 2507).

Performance Enhancing Proxies

PEPs are used to improve the performance of the Internet protocols on networks paths in which native performance suffers from characteristics of the links or subnetworks on the path. PEPs provide a safe mechanism to leverage the problems of TCP over satellite links, and have become the de facto solution on field (Kota, Pahlavan, and Leppanen 2003). They are typically implemented at the transport or application layer, although some cross-layer implementations exist. PEPs may be classified based on symmetry and transparency. Examples of transport layer PEPs are TCP spoofing and TCP connection-split proxies. In both PEP types, the goal is to shield high-latency or lossy satellite network segments from the rest of the network in a transparent way to the applications. Strictly speaking, *splitting* refers to breaking up a connection and *spoofing* refers to imitating the end point of the TCP connection.

TCP Spoofing

In TCP spoofing, a router (gateway) near the source sends back ACKs for TCP segments to give the source the

illusion of a short delay path and therefore speed up the sender's data transmission. It then suppresses the true acknowledgment stream from the satellite host and takes responsibility for sending any missing data. However, unlike a TCP proxy, spoofing is transparent to both the sender and receiver.

TCP Splitting

Split, or cascading, TCP is a scheme in which a TCP connection is divided into multiple TCP connections, with a special connection running over the satellite link. The idea is that the TCP running over the satellite link can be modified, with the knowledge of the satellite's properties, to run faster. Because each TCP connection is terminated, cascading TCP is not vulnerable to asymmetric paths. It works well in cases where applications actively participate in TCP connection management (e.g., Web caching). In other cases, split TCP has the same problems as TCP spoofing.

PEP Mechanisms

PEP mechanisms include ACK spacing, local acknowledgments, local transmissions, tunnels to control routing of packets, header compression, payload compression, and priority-based multiplexing. Many TCP PEPs use TCP ACK manipulation.

Some other PEPs acknowledge TCP segments locally in order to mitigate the effect of long RTT, which speeds up the slow start—the main mechanism used in TCP spoofing. Local negative acknowledgments are also used to trigger local and fast error recovery. Local ACKs are used in PEPs with split connections. When local ACKs are used, and the data are dropped after being acknowledged by the PEP, it is the PEP's responsibility to recover the data. In this case, the PEP has to use local TCP retransmission to the receivers.

Recent TCP Enhancements

Satellite Transport Protocol

STP is a reliable, byte-oriented transport protocol that was designed to perform well over satellite links. The STP sender and receiver use buffer sizes that are of the order of the bandwidth-delay product of the links. STP mechanisms lead to low reverse channel bandwidth usage when losses are rare and to speedy recovery in the event of loss.

WISE

The wireless IP suite enhancer (WISE), which was developed at Lincoln Laboratory, improves the performance of TCP/IP protocol suite in a wireless environment, increasing the wireless link utilization. The WISE approach consists of software that is added to gateways at the periphery of the wireless segment of the network. These software components convert TCP to wireless link protocol (WLP) upon entering the wireless subnetwork and back to TCP upon exiting. WLP is a special transport protocol developed according to the physical characteristics of the wireless link at hand, and addresses the issues faced by TCP over wireless links.

Quick-Start TCP

Quick-start TCP introduces a new mechanism for transport protocols to determine an optional allowed initial congestion window at the start of data transmission. The source indicates its initial desired rate in packets per second by sending a quick-start request option in the IP header of the initial TCP SYN or SYN/ACK packet.

TCP-Peach and Improvements

TCP-Peach is based on the replacement of slow-start and fast recovery algorithms with sudden-start and rapid-recovery procedures, which rely on the introduction of dummy segments to probe the availability of the network resources to improve the network performance when segment losses are a result of link error instead of congestion. Subsequently, TCP-Peach has been improved to TCP-Peach+ for satellite IP networks. TCP-Peach+ includes the following new schemes: jump start and quick recovery, and two classical algorithms, congestion avoidance and fast retransmit. The TCP SACK option is also adopted in TCP-Peach+ to improve the performance when multiple segments are lost from one window of data. Recently, an enhancement to TCP-Peach+, called TCP-Peach++, has been proposed to improve the throughput performance for satellite IP networks with asymmetrical bandwidth and persistent fades. The delayed SACK scheme has been adopted to address the problems caused by bandwidth asymmetrical satellite links. A new protocol procedure, hold state, was developed to address the link outages caused by persistent fades. Performance evaluation shows that TCP-Peach++ effectively addresses these challenges and hence improves the throughput in satellite IP networks (Fang and Akan 2005).

TCP Westwood and Improvements

The key innovation of TCP Westwood (TCPW) is the use of bandwidth estimate to directly drive cwnd and slow-start threshold (ssthresh). The TCP sender continuously monitors ACKs from the receiver and computes its current eligible rate estimate (ERE). ERE is based on the rate of ACKs and their payload. Upon a packet loss indication (3DUPACKs or a time-out), the sender sets the cwnd and ssthresh based on ERE.

TCP-Friendly Congestion Control

Many real-time, less loss-sensitive services and applications that rely on transport protocols (e.g., UDP and RTP) are rapidly spreading over IP networks. This incurs a cohabitation issue: during congestion, TCP flows reduce data rates to release the congestion, but the non-TCP flows continue to send at the original rate. This leads to starvation of TCP traffic or even to a congestion collapse. To avoid such a situation, TCP rate adaptation rules are being defined to make non-TCP applications TCP friendly, thereby leading to a fair distribution of bandwidth.

TPC with Byte Counting and Improvements

This enhancement is designed to counter the effects of delayed ACKs on TCP throughput (RFC 2414, 3465). Delayed ACKs increase the time needed by the TCP sender to increment the congestion window during slow start.

Byte counting proposes to increase the congestion window based on the number of transmitted bytes acknowledged by incoming ACKs rather than on the number of ACKs received. In this way, the congestion window is opened according to the amount of data transmitted, rather than the receiver's ACK interval, and throughput may be increased.

TCP for Asymmetric Channels

With asymmetric channel capabilities such as ADSL and DVB increasingly being deployed as high-speed Internet access networks, several mechanisms have been proposed to improve the efficiency of TCP over those channels. These include header compression, reducing the frequency of TCP ACKs, and traffic scheduling optimization.

Scalable TCP

Scalable TCP (S-TCP) is a recent proposal that focuses on modifying the TCP congestion control algorithm in order to improve performance in high-speed backbone networks (Miorandi and Giambene 2005). Like TCP, S-TCP is based on a sliding window mechanism for controlling the transmission rate. It is based on a multiplicative increase, multiplicative decrease (MIMD) algorithm. S-TCP gets its name from the fact that the time it takes to recover from a loss is independent of the congestion window. Similarly, high-speed TCP (HSTCP) has been proposed recently by Floyd for networks with a very large bandwidth-delay product (BDP) such as satellite networks (RFC 3649). The congestion control algorithm of HSTCP can be characterized as an aggressive AIMD behavior. Because both S-TCP and HSTCP are sender-based modification, they can exploit SACK capabilities (RFC 2018), whose use can improve the system performance in the presence of bursty losses in the same window of data.

REFWA

The recursive, explicit, and fair window adjustment (REFWA) scheme is presented as a solution to improve the efficiency and fairness of TCP in NGEOS systems. An improvement to the REFWA scheme, REFWA Plus, is also used to combat link errors in satellite environments (Marchese and Jamalipour 2005).

Others

Various other TCP variants and enhancements have been proposed recently: TCP-DCR, proposed in Bhandarkar et al. (2005) introduces a set of simple modifications to the TCP protocol to improve its robustness to channel errors in wireless networks. It is based on the simple idea of allowing the link-level mechanism to recover the packets lost due to channel errors, thereby limiting the response of the transport protocol to primarily congestion losses. TCP-DCR delays responding to a packet loss indication by a small period of time (one RTT) to allow channel errors to be recovered by link-level retransmission. An interesting by-product of using TCP-DCR is the inherent robustness it provides against degradation due to packet re-ordering in the network. Another recent TCP variant proposal, addressing the long RTT issue in heterogeneous networks, is TCP-Hybla (Caini and Firrincieli 2004). In heterogeneous

networks, TCP connections that incorporate a terrestrial or satellite radio link are greatly disadvantaged with respect to entirely wired connections because of their longer round-trip times. TCP-Hybla suggests the necessary modifications to remove the performance dependence on RTT. TCP-Hybla was found to be superior in all of the examined cases because it greatly reduces the severe penalization suffered by wireless and satellite connections. In addition to simulation works, Bisio and Marchese (2004) provide an analytical expression for TCP packet loss probability over GEO channels.

Ultimately, the use of basic TCP in future broadband satellite networks will impose significant problems, especially in the case of short transmissions (compared with the channel delay-bandwidth product). For GEO satellite links, the major problem with TCP is the long round-trip time, whereas in the case of NGSO satellite networks, the round-trip delay variation or jitter becomes more dominant. In both situations, the burst-error nature of the satellite channel and the high BER require more sophisticated flow and congestion-control mechanisms that can separate the segment loss because of network congestion or because of high channel error rate.

CONCLUSION

In this chapter, we summarized the satellite communications from a networking point of view in order to observe the role of satellites in future mobile and fixed IP networks. The historical summary provided in the first section of this chapter revealed that despite the high initial investment and maintenance costs of satellite systems, satellites will remain an irreplaceable component of long-distance communications and multimedia broadcasting. In recent years, as a result of the progress in optical communications and the increasing number of transoceanic cables, it may have been mistakenly thought that cable would replace the satellite for long-distance communications. However, the satellite's easy and quick deployment of additional capacity in any part of the world provides a distinct advantage over the deployment of cable systems. Improvement in cable television also could not replace satellite's broadcasting feature, especially due to the satellite's large footprint and simpler deployment.

When it comes to high-speed Internet access to the home, office, ships, aircrafts, and mobile users, again satellite systems show their unique features. The global Internet needs expansion both in the geographical domain and in data-transport capacity. Satellites are the main telecommunications component, if not the only one (in many terrain circumstances), that can promise such expansion. A satellite with huge on-board channel capacity and a large coverage area is sufficient to provide future deployment of new systems. A very handy example is the effort toward the realization of in-flight Internet access and VoIP services to passengers using satellite networks by major airlines and fast trains.

For high-speed Internet access to the home and small office users, currently ADSL and cable modems are the two leading technologies. With the advent of new digital video broadcasting satellite systems in North America and Europe, however, these technologies have had to compete

with satellites. The number of subscribers to satellite high-speed Internet access is increasing and growing close to the other two technologies; this number is expected to increase even more rapidly with the introduction of inexpensive satellite receivers in the next few years.

Satellites have made an even larger contribution to IP networks than to individual access. A satellite node can be an intelligent ATM switch or IP router in the sky, interconnecting segments of the backbone networks on Earth. Similar to the conventional usage of satellites in public switched telephony networks, satellites can play important roles in future packet-switched networks, including the public Internet. 3G and B3G wireless networks consider Internet and multimedia traffic to have the dominant share of the network traffic load, and satellites have already shown their role in the completion of any terrestrial mobile network. An example of satellite UMTS was given in this chapter to outline the role of satellites in 3G wireless systems. Satellite ground stations acting as an interworking unit can solve the roaming issue between heterogeneous wired and wireless terrestrial networks, expanding the telecommunications to its ultimate universal stage.

Some important technical implementation issues concerned with a global IP network have been discussed in this chapter. Physical layer, medium access and mobility management, QoS, IP multicast, VoIP, and security issues have been discussed with regard to satellite IP networks. All of these issues are current research topics, both in mobile and satellite communications. For the high-latency satellite channel, as well as the error-prone wireless channel (including both satellite and terrestrial), the need for improvement in transport protocols currently employed in the Internet has been discussed, and state-of-the-art research activities toward improvement of TCP protocols have been reviewed. Note that researchers are also working to improve the error probability of the wireless channel using forward error correction schemes and sophisticated coding algorithms. Although these works are of great importance to the establishment of a better-quality wireless channel, we should not forget there are always situations in which the wireless signal-to-noise ratio is too low and no coding scheme can improve it. Therefore, a better solution lies in the higher layers of the network, including the transport and network layers, where enhanced flow control algorithms speed up the data rate and the throughput of the wireless channel.

ACKNOWLEDGMENT

GLOSSARY

- 2G:** Second-generation wireless mobile cellular systems, mainly consisting of global system for mobile communications (GSM) and CDMAOne.
- 3G:** Third-generation wireless mobile cellular systems, mainly consisting of universal mobile telecommunications system (UMTS) and CDMA2000.

B3G: The temporary name for systems under development that are beyond third generation wireless mobile cellular systems; sometimes referred to as fourth generation (4G).

DAB: Digital audio broadcasting; a technique used to transmit high-quality audio signals (e.g., radio) digitally, usually by satellite.

DVB: Digital video broadcasting; a technique used to transmit high-quality video signals (e.g., television) digitally, usually by satellite.

GEO Geostationary Earth orbit; a space orbit at about 36,000 km over Earth at which satellites may be seen from Earth as stationary objects.

Handover: Change that involves switching service from one base station to another one for a mobile user during movement; sometime referred to as handoff.

Heterogeneous Networks: Networks that consist of different types of systems (e.g., cellular, wireless LAN, etc.).

IP: Internet protocol; the main protocol used in the Internet at the network layer (layer 3); currently in version 4 (IPv4) but moving toward implementation of IPv6.

ISL: Intersatellite link; a link between adjacent satellites on an orbit or planes to provide inter-connectivity among satellites usually used in LEO satellite systems.

LEO: Low Earth orbit; a space orbit at about 1000 km over Earth at which a satellite can orbit Earth at high speeds and may be seen from Earth as a fast-moving object.

MAC: Medium access control; the protocol at layer 2 of the network to control and govern network access by multiple users.

MEO: Medium Earth orbit; a space orbit above LEO and below GEO at which a satellite will be seen from Earth as a moving object.

Mobility Management: A set of techniques that controls the movement of a mobile device within a network and is usually composed of two elements: location management and handoff management techniques.

QoS: Quality of service; maintaining the required service condition to a user in a network (e.g., providing a maximum delay or minimum data-rate speed).

Resource Management: A set of management techniques in a network to ensure that available resources—as required by the end terminal application—can be offered between peer end terminals, and how to make sure that resource allocation takes into consideration the current network conditions.

RSVP: Resource reservation protocol; a reservation control mechanism to provide quality of service to users by reserving resources beforehand; usually used in the Internet QoS establishment.

Satellite Communications: A network of spacecraft for providing telecommunications services.

TCP: Transmission control protocol; the vastly used transport protocol for the Internet that provides reliable data transfer among Internet terminals.

UDP: User datagram protocol; the transport protocol for the Internet that provides lower delay compared with TCP—at the expense of lower reliability—and is

used for short message transfers or delay-sensitive applications.

VoIP: Voice over IP; a technique to deliver delay-sensitive voice packets over the Internet that can provide lower costs to users.

INTRODUCTION

Satellite navigation systems have become an integral part of all applications in which mobility plays an important role (Heinrichs et al. 2005). These functions will be at the heart of the mobile phone third-generation (3G) networks such as the Universal Mobile Telecommunications System (UMTS). In transportation systems, the presence of receivers will become as common as seat belts or airbags, with all car manufacturers equipping their entry-level vehicles with these devices.

As for past developments, GPS launched a variety of techniques, products and, consequently, applications and services. The milestone of satellite navigation is the real-time positioning and time synchronization. For that reason the implementation of wide-area augmentation systems should be highlighted, because they allow significant improvement in accuracy and integrity performance. WAAS, EGNOS, and MSAS provide—over the United States, Europe, and Japan respectively—a useful augmentation to GPS, GLONASS, and Galileo services (Mulassano et al. 2004).

GNSS development has an interesting aspect due to its sensitive nature. Considerable events or developments are always subject to a couple of differentiators: technological developments and political decisions. In all stages of improvements, GPS and GLONASS are strictly related to those differentiators. The approval and startup of the European Galileo program is considered by far the most real innovation. It is intended that the Galileo satellite navigation system will offer improved accuracy, availability, continuity, integrity, and general robustness over the existing GPS system (GALILEO 2003; Feng 2003). Consequently, much rests on current design and development efforts to ensure the intended performance of Galileo and its value added services, particularly for the certified safety services. Technological and political decisions in Galileo substantiate that interoperability

and compatibility must be achieved in forthcoming years. Such issues are true GNSS improvement for the benefit of institutions and organizations.

GNSS applications in all fields will play a key role, moving its use from the transportation domain to multimodal use, outdoors and indoors. It is expected that GNSS will increase significantly the precision in position domain (Lachapelle et al. 2002). For the wider community, the combined (and competitive) benefits of GPS and Galileo will result in major improvements in navigation, timing and related applications, and services.

To realize these benefits, a range of Galileo receivers (based on flexible system design principles and equally flexible implementation) must be made available, in time to enable the commercial exploitation and market penetration of the Galileo system and services.

The concept of a reference system for navigation is essential because GNSS and all its applications are related to the coordinate system used. The main application of GNSS is the determination of position in the global reference system any where, any time on the globe in a simple, fast, and cost-effective manner.

The integration of GNSS and other related technologies such as telecommunications (GSM, GPRS, and UMTS), the Geographic Information Systems (GIS), and Inertial Navigation System (INS) has created numerous applications that need more time to be discussed in detail. Many research efforts have been exerted in order to find new applications to promote the quality of our lives through the benefits of GNSS (Lohnert et al. 2001; Al-Bayari and Sadoun 2005).

GNSS COMPONENTS

GNSS consists of three main satellite technologies: GPS, GLONASS, and GALILEO. Each of them consists mainly of three segments: (a) space segment, (b) control segment, and (c) user segment.

These segments are almost identical in the three satellite technologies, which together make up the GNSS. As of today, the complete satellite technology is basically GPS technology and most of the existing worldwide applications are related to GPS technology. The GNSS technology will become clearer after the operation of GALILEO and the reconstruction of GLONASS by the end of 2008.

Global Positioning System

The United States Department of Defense (DoD) has developed the GPS, which is an all-weather, space-based navigation system to meet the needs of U.S. military forces and accurately determine their position, velocity, and time in a common reference system, any where on or near the Earth on a continuous basis (Wooden 1985).

GPS has made a considerable impact on almost all positioning, navigation, timing, and monitoring applications. It provides particularly coded satellite signals that can be processed in a GPS receiver, allowing the receiver to estimate position, velocity, and time (Hofmann-Wellenhof et al. 2001). There are a minimum of four GPS satellite signals that are used to compute positions in three dimensions and the time offset in the receiver clock. GPS comprises three main components:

- Space segment: The space segment of the system consists of the GPS satellites; see Figure 1 below. Space vehicles (SVs) send radio signals from space as shown in Figure 2.
- Control segment: The control segment consists of a system of tracking stations located around the world. The Master Control facility is located at Schriever Air Force Base (formerly Falcon AFB) in Colorado.
- User segment: The GPS user segment consists of the GPS receivers and the user community. GPS receivers convert space vehicle (SV) signals into position, velocity, and time estimates.

The satellites are dispersed in six orbital planes on almost circular orbits with an altitude of about 20,200 km above the surface of the Earth, inclined by 55 degree with respect to the equator and with orbital periods of approximately 11 hours 58 minutes (half a sidereal day).

GPS CONSTELLATION

21 SATELLITES WITH 3 OPERATIONAL SPARES
6 ORBITAL PLANES, 55 DEGREE INCLINATIONS
20,200 KILOMETER, 12 HOUR ORBITS

Figure 1: Nominal GPS constellation

GPS SATELLITE SIGNALS

Figure 2: GPS satellite signals

The categories are Block I, Block II, Block IIR (R for replenishment), and Block IIA (A for advanced) and a further follow-up category Block IIF has also been planned (ICD-GPS, 2003). Figure 3 shows the main GPS segments.

GPS Signals

The generated signals on board the satellites are based on or derived from generation of a fundamental frequency $f_0 = 10.23$ MHz (Hofmann-Wellenhof et al. 2001). The signal is controlled by atomic clock and has stability in the range of 10^{-13} over one day. Two carrier signals in the L-band, denoted L1 and L2, are generated by integer multiplications of f_0 . The carriers L1 and L2 are biphasic modulated by codes to provide satellite clock readings to the receiver and transmit information such as the orbital parameters. The codes consist of a sequence with the states +1 or -1, corresponding to the binary values 0 or 1. The biphasic modulation is performed by a 180° shift in the carrier phase whenever a change in the code state occurs; see Figure 4. The clear/access code (C/A-code) and precision code (P-code) are used for the satellite clock reading, both characterized by a pseudorandom noise (PRN) sequence. The W-code is employed to encrypt the P-code to the Y-code when Anti Spoofing (A-S) is applied. The navigation message is modulated using the two carriers (L1 and L2) at a chipping rate of 50 bps.

It contains information about the satellite orbits, orbit perturbations, GPS time, satellite clock, ionospheric parameters, and system status messages (Leick 2003). The modulation of L1 by P-code, C/A-code, and navigation message (D) is done using the quadrature phase shift keying (QPSK) scheme. The C/A-code is placed on the L1 carrier with 90° offset from the P-code because they have the same bit transition epochs. For the L1 and L2 we have:

$$\begin{aligned} L1(t) &= a_1 P(t) W(t) \cos(2\pi f_1 t) + a_1 C/A(t) D(t) \sin(2\pi f_1 t) \\ L2(t) &= a_2 P(t) W(t) \cos(2\pi f_2 t) \end{aligned} \quad (1)$$

The signal broadcast by the satellite is a spread spectrum signal, which makes it less prone to jamming. The basic concept of the spread spectrum technique is that the information waveform with small bandwidth is converted by modulating it with a large-bandwidth waveform (Hofmann-Wellenhof et al. 2001).

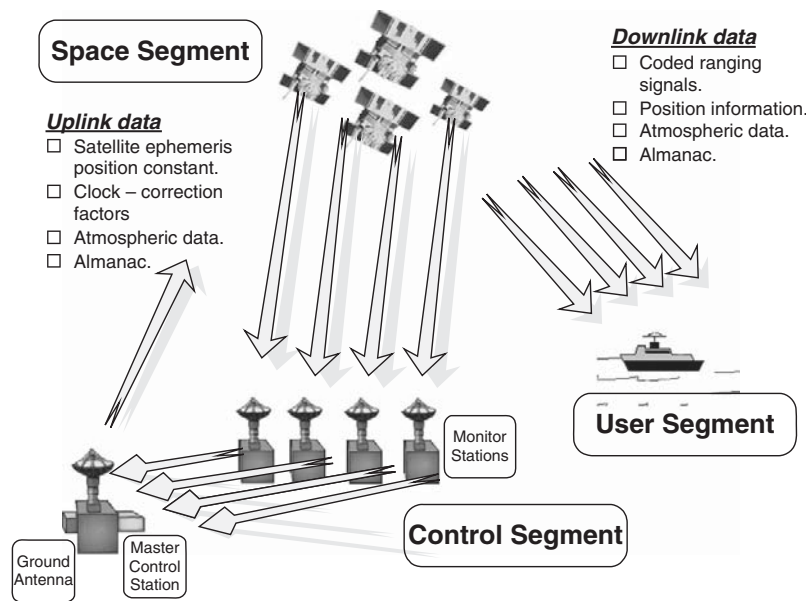

Figure 3: GPS segments (Aerospace Corporation, 2003)

Figure 4: Biphase modulation of carrier

The generation of pseudo random sequence (PRN) in the code is based on the use of an electronic hardware device called tapped feedback shift register (FBSR). This device can generate a large variety of pseudo random codes, but in this way the generated code repeats itself after a very long time. The receiver can distinguish the signals coming from different satellites because the receiving C/A code (the Gold code), has low cross-correlation and is unique for each satellite (Leick 2003). The navigation message consists of 25 frames, with each frame containing 1,500 bit, and each frame is subdivided into 5 sub-frames with 300 bit. The information transmitted by the navigation message is periodically updated by the control segment.

Modernized GPS

Due to the vast civil applications of GPS technology during the past decade or so and due to the new technologies

used in satellites and receivers, the U.S. government has decided to extend the capabilities of GPS to provide more benefits to the civil community. In addition to the existing GPS signals, new signals will be transmitted by GPS satellite; see Figure 5. Moreover, this will increase the robustness of the signals and improve resistance to signal interference. This will definitely lead to better quality of service (QoS). The new signals added to the GPS (Fontana et al. 2001), are: (i) a new L5 frequency in an aeronautical radio navigation service (ARNS) band with a signal structure designed to improve aviation applications, (ii) C/A code to L2C carrier (L2 civil signal) and (iii) a new military (M) code on L1 and L2 frequency for DoD applications. It has the potential to track signal even in poor conditions where the C/A code tracking on L1 would not be possible. The new military code will be transmitted from the Block IIR-M and IIF satellites (Betz 2002).

It is well known that the presence of dual frequency measurements (L1 and L2) has good advantages for eliminating the effect of the ionosphere and enhancing the ambiguity resolution, especially for the high-precision measurements (Liu and Lachapelle 2002). High-end civil dual frequency systems will be based on L1 CA-code and the newly designed L2 C-code. In the coming few years, the receivers will become more complex in order to allow tracking the new civil code on L2 and tracking the encrypted P on L2 (A-S).

The frequency of L5 is 1,176.45MHz, with a chipping rate of 10.23 MHz similar to P-code. The high chipping rate

1. Adds L2C to L2.

2. Adds new military M – Code.

3. Adds civil L5.

Signals in Space

Figure 5: Modernized GPS signals

of L5 code will provide high performance ranging capabilities and better code measurement than L1 C/A code measurements (Dierendonck and Hegarty 2000).

L2 has better correlation protection with respect to L1 because it has a long code. This will be useful in severe conditions where the GPS signals are weak, such as navigation in urban, indoor, and forested areas.

The old codes and the new codes (military and civil), on the L1, L2, and L5 need more advanced modulation so as to better share existing frequency allocations with all signals by increasing spectral separation, and hence conserve the spectrum. Consequently, the binary offset carrier (BOC) is used for the military code modulations (Betz 2002).

GLONASS

The GLONASS (GLObal NAVigation Satellite System or "GLObalnaya NAVigatsionnaya Sputnikovaya Sistema") is nearly identical to GPS. The GLONASS satellite-based radio-navigation system provides positioning and timing information to users. It is operated by the Ministry of Defense of the Russian Federation (GLONASS-ICD, 2002).

The GLONASS space segment consists of 24 satellites, equally distributed in 3 orbits separated by 120° in the equatorial plane. Satellite orbital altitude is about 19,130 km above the ground surface. This results in an orbital period of 11:15:44, corresponding to 8/17 of a sidereal day.

The future of GLONASS seems uncertain due to economic problems facing the Russian Federation. The number of operational satellites was steadily decreasing over the past few years. The launch of three new GLONASS satellites in December 1998 was the first launch after a lapse of 3 years.

The Signals of the GLONASS Satellites

GLONASS satellites transmit C/A-code on L1, and P-code on L1 and L2. GLONASS observables (code and phase) are similar to GPS. The main difference between GPS and GLONASS is that GLONASS uses Frequency Division Multiple Access (FDMA) technology to discriminate among the signals of different satellites, but GPS and GALILEO use Code Division Multiple Access (CDMA) to distinguish among the satellites. All GLONASS satellites transmit the same C/A- and P-codes, but each satellite has slightly different carrier frequencies.

The nominal carrier frequencies for the L1 and L2 signals may be written as shown below (Leick 2003):

$$\begin{aligned} f_1^n &= 1602 + 0.5625 \cdot n \text{ MHz} \\ f_2^n &= 1246 + 0.4375 \cdot n \text{ MHz} \end{aligned}$$

with

$$\frac{f_1^n}{f_2^n} = \frac{9}{7}$$

where n is the frequency channel number $1 \leq n \leq 24$, covering a frequency range in L1 from 1602.5625 MHz to 1615.5 MHz. Because some of the GLONASS frequencies interfere with frequencies used for radio-astronomy, some changes in the frequency plan are expected after 2005 (GLONASS-ICD 2002). The navigation message is contained in the so-called sub frames, which have duration of

2.5 minutes. Each sub frame consists of five frames with a duration of 30 seconds. The navigation message contains information, similar to GPS navigation message, about the satellite orbits and their clocks, among others.

In contrast to GPS, where the broadcast ephemerides are defined by modified Keplerian elements, the broadcast ephemerides of GLONASS satellites are defined by positions and velocities referred to as Earth-centered and Earth-fixed systems (PZ-90). The broadcast ephemerides of the GLONASS satellites are updated every 30 minutes.

Modernized GLONASS

According to Russian officials, the GLONASS system will be restored by 2008. The second generation GLONASS-M was launched at the end of 2004, and launch of the third generation GLONASS-K satellites is planned for 2007/2008.

As of April 2006, a total of 12 GLONASS satellites are operational with 2 GLONASS-M.

The important advantage of GLONASS-M is the ability to broadcast the civil L2 signal that can be treated as an analog of L2C GPS signal. The structure of the new signal is the same as the structure of GLONASS C/A L1 signal. Unlike GPS, GLONASS does not encrypt its P-code signals; thus, today civil receivers can use GLONASS P-code "free of charge."

GLONASS-K will have extended lifetime of 10 years, and will be capable of broadcasting L3 civil signal, on which integrity information for safety-of-life applications is available.

GALILEO

GALILEO is Europe's initiative for a state-of-the-art global navigation satellite system, providing a highly accurate, guaranteed global positioning service under civilian control. GALILEO will not be too different from the other GNSS parts, modernized GPS, and GLONASS (Salgado et al. 2001). GALILEO will provide autonomous navigation and positioning services, but at the same time will be interoperable with the two other global satellite navigation systems; the GPS and GLONASS. A user will be able to take a position with the same receiver from any of the satellites in any combination. By providing dual frequencies as standard, however, GALILEO will deliver real-time positioning accuracy down to the meter range. It will guarantee availability of the service under all but the most extreme circumstances, and will inform users within seconds of the failure of any satellite. This will make it appropriate for applications where safety is vital, such as running trains, guiding cars, and landing aircraft. The combined use of GALILEO and other GNSS systems can offer much-improved performance for all kinds of users worldwide. GALILEO is expected to be in operation by the year 2008. The first satellite of the GALILEO system (GIOVE A) was launched on December 27, 2005.

GALILEO segments

GALILEO segments are similar to GPS, but with some modification. The main extension of GALILEO, compared to GPS, is the implementation of a global/regional segment for integrity monitoring. The objective is to improve

the safety of critical aircraft navigation, as well as locate and guide railway trains (GALILEO 2003).

Space Segment. The space segment or the constellation features consists of 30 Medium Earth Orbiting (MEO) satellites (27 and 3 active spare satellite), distributed evenly and regularly over three orbit planes. The projected altitude is slightly larger than for GPS 23,616 km and the inclination is 56 degrees (Benedicto and Ludwig 2002).

Ground Segment. The GALILEO ground segment is responsible for managing the constellation of navigation satellites, controlling core functions of the navigation mission such as orbit determination of satellites and clock synchronization, and determining and disseminating (via the MEO satellites) integrity information, such as the warning alerts within time-to-alarm requirements, at global level. The global ground segment will also provide interfaces with service centers. The Ground Control Segment will consist of about 12 to 15 reference stations, 5 up-link stations, and 2 control centers. The ground segment also will include 16 to 20 monitor stations, 3 up-link stations for integrity data, and 2 central stations for integrity computations.

User Segment. The user segment consists of different types of user receivers, with various capabilities related to the different GALILEO signals, in order to fulfill the various GALILEO services; see Figure 6.

GALILEO Signals

The GALILEO frequency should respect and adhere to the radio-regulations discussed and agreed upon at the International Telecommunications Union (ITU) forums, such as the World Radio-Communication Conference (WRC).

Various studies were conducted before determination of the Galileo signal allocations in order to avoid interference with GPS and Glonass systems, which operate in the same portion of the RF spectrum (Hein et al. 2003).

Galileo will provide several navigation signals in right-hand circular polarization (RHCP) in the frequency ranges of 1164–1215 MHz (E5a and E5b), 1260–1300 MHz (E6) and 1559–1592 MHz (E2-L1-E1) that are part of the Radio Navigation Satellite Service (RNSS) allocation (Hein et al. 2003, GALILEO-ICD 2006). All GALILEO satellites will share the same nominal frequency, making use of code division multiple access (CDMA) techniques. GALILEO will use a different modulation scheme for its signals, the binary offset carrier (BOC), alternate BOC (AltBOC) and quadrature phase shift keying (QPSK). AltBOC modulation scheme is based on the standard BOC modulation.

Definition of Services

The GALILEO constellation offers the capability of globally broadcasting a set of six signals supporting the open, commercial, safety-of-life, and public regulated services (Hein et al. 2003). Each navigation signal is composed of one or two ranging codes and navigation data as well as, depending on the signal, integrity, commercial, and search and rescue (SAR) data. Satellite-to-user distance measurements based on ranging codes and data are used in the GALILEO user receivers to fulfill the different GALILEO services (GALILEO 2003). The main services are:

1. Open service (OS) data: These are transmitted on the E5a, E5b, and E2-L1-E1 carrier frequencies. OS data are available to all users and consist mainly of the navigation and SAR data. Open service offers positioning,

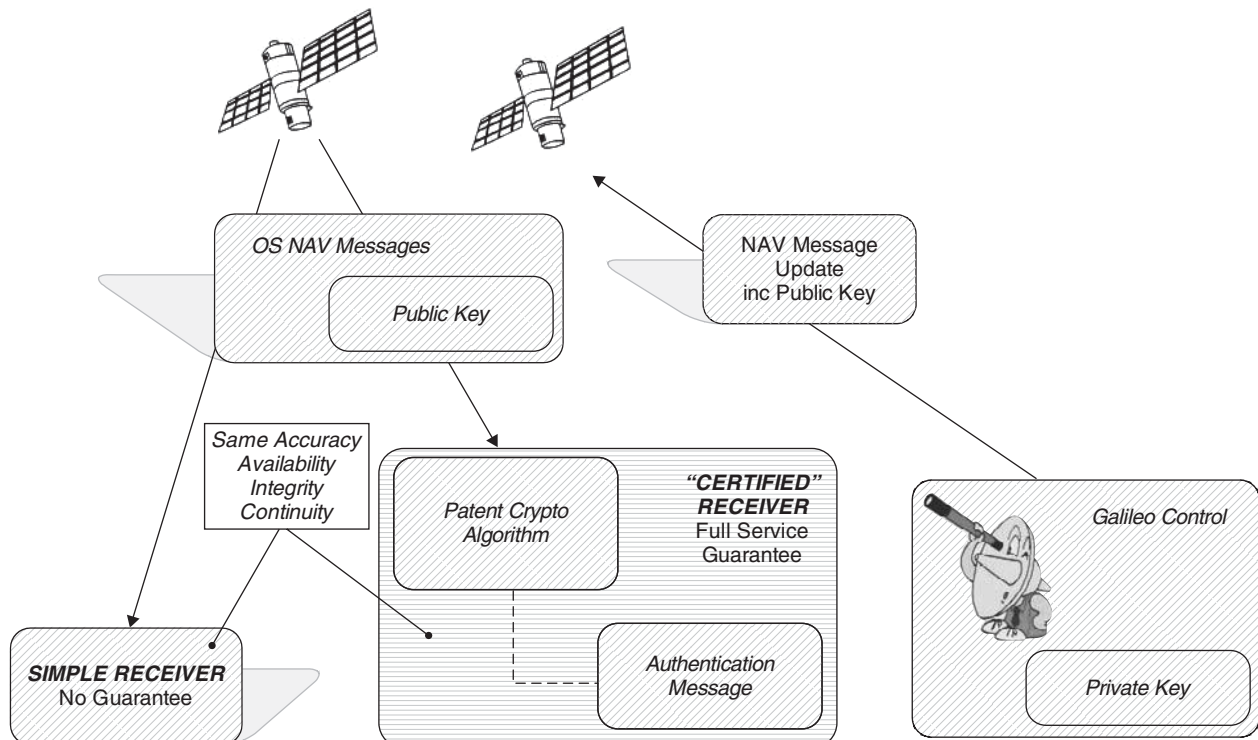

Figure 6: GALILEO system architecture (GALILEO 2003)

navigation and timing signals, which can be accessed free of charge.

2. **Commercial Service (CS), data:** These are transmitted on the E5b, E6, and E2-L1-E1 carriers. All CS data are encrypted and provided by service providers that interface with the Galileo Control Centre. Access to those commercial data is provided directly to the users by the service providers. The signal is designed to support very precise local differential applications (Sub-meter accuracy) using the open (option encrypted) signal overlaid with the Public Regulated Service (PRS) signal on E6, as well as to support the integration of GALILEO positioning applications and wireless communications networks.
3. **Safety-of-life Services (SOL) data:** These include mainly integrity and Signal in Space Accuracy (SISA) data. Combination of this Galileo services either with the current GPS as augmented by EGNOS corrections, or the future improved GPS and EGNOS integrity-only. Particularly, SOL is based on the satellite navigation signals without using added elements such as WAAS, and EGNOS. The accuracy required is about 4 meters over the globe. This could be possible by introducing the ionospheric model based on multiple frequency measurements and modeling the other GNSS errors.
4. **Public Regulated Service (PRS) data:** These are transmitted on E6 and L1 carrier frequencies. The Public

Regulated Service is provided on dedicated frequencies to provide the capability for greater continuity of service placed under EU Governments' control for Public applications devoted to European and/or National Security, such as police, civil protection, law enforcement, civil protection (such as some emergency services) as well as other governmental activities. The PRS is robust in order to be resistant to interference, jamming, and other accidental or malicious aggressions.

GNSS SIGNALS

The signals of Modernized GPS, GALILEO, and GLONASS systems make up the GNSS signals (Table 1). Each satellite system has specific signal characteristics, but each system attempts to be compatible with the others in order to prevent the interferences and attenuation between the signals. It is important to consider that the processing of all signals should be performed using the same receiver; thus a complex receiver design is supposed to be designed and built. As mentioned above, the GNSS frequency plan will respect the radio-regulations as they are discussed and agreed upon on at ITU forums. The available spectrum which can be used for the development of Radio-Navigation Satellite Systems (RNSS) is shown in Figure 7.

On the 20th to 22nd of March 2006, (Galileo-ICD 2006), the GPS-Galileo Working Group on Radio Frequency

Table 1: GNSS Signals

System	Signal	Modulation type	Chip rate Mcps	Frequency MHz
GPS	L1	BPSK	1.023	1575.42
	L2	BPSK	1.023	1227.6
	L5	QPSK	10.23	1176.45
GLONASS	L1	BPSK	0.511	1602.5625 – 1615.5
	L2	BPSK	5.110	1246.4375 – 1256.5
GALILEO	E1	BOC	1.023	1575.42
	E5	AltBOC	10.23	1191.795
	E6	BPSK	5.115	1278.75

Figure 7: Radio-Navigation Satellite Systems (RNSS) frequency spectrum defined for GNSS signals (GALILEO 2005)

Compatibility and Interoperability successfully proposed a jointly-optimized common Power Spectral Density for Galileo Open Service (OS) and GPS L1C signals in L1 band, denoted as Modified Binary Offset Carrier (MBOC) in Stockholm, Sweden.

SIGNAL PROCESSING AND RECEIVER DESIGN

The main function of the signal processor in the receiver is the reconstruction of the carriers and extraction of codes and navigation messages. After this stage, the receiver performs the Doppler shift measurement by comparing the received signal to a reference signal generated by the receiver. Due to the motion of the satellite, the received signal is Doppler shifted.

The code ranges are determined in the delay lock loop (DLL) by using code correlation. The correlation technique provides all components of bimodulated signals. The correlation technique is performed between the generated reference signal and the received one (Hofmann-Wellenhof et al. 2001). The signals are shifted with respect to time so that they are optimally matched based on mathematical correlation.

Currently some geodetic type receivers are available on the market that track GPS and Glonass satellites simultaneously on both frequencies, in particular the Ashtech Z18 receiver and the TPS (Topcon Positioning Systems) Legacy receivers. The future GNSS receiver could be designed to track the different GNSS signals and could be of many types including:

- The first type could process all GNSS signals GPS L1, L2, L5, and GALILEO OS, CS using L1, E5, and E6 as well as GLONASS L1 and L2.
- The second type uses free signal and codes, GPS L1 and L2C and GALILEO OS, on L1 and E5.
- The third type uses L1 and E5.
- The fourth type uses GPS L1 and L2, which are already on the market (Ries et al. 2002).
- The fifth type uses GPS and GLONASS signals, which already exist (Leick 2003).

The most common receiver types are Intermediate Frequency receiver (IF) and the software defined radio receiver (SDR). In the RF front-end receiver, the signal is

down converted to an intermediate frequency and then sampled, but SDR uses direct digitization, or bandpass sampling. (Details on GNSS receiver design can be found in Schmid et al. 2004, and in Julien et al. 2004a).

The main components of the RF-FE combined GNSS receiver are shown in Figure 8. After sampling and analog-to-digital conversion (ADC) of the received signal, the receiver performs parallel de-spreading. The received base-band signal is multiplied in parallel with the spreading codes of all visible satellites. The received signal of each satellite is multiplied in parallel with different code delay offsets. These products are then accumulated to compute the cross-correlation function.

Because BOC signals are used in GALILEO, supplementary measures are necessary due to the multiple correlation peaks of the auto-correlation function. Carrier tracking is performed using a phase-locked or frequency-locked loop (PLL or FLL). Coherent correlation combined with differential or non-coherent correlation can be done for the pilot and the data channel (Schmid et al. 2004). Multiple signals will be available at L1 within the next few years (Hein et al. 2004). Galileo will use a different modulation scheme, such as BOC and QPSK, for its signals, while GPS uses binary phase shift keying (BPSK) modulation for the open signals at L1 and L2. The L5 signal that will appear with the Block IIF satellites in 2006 will have quadrature phase shift keying (QPSK).

The binary offset carrier (BOC) modulation scheme of Galileo provides better multipath and receiver noise performance compared to the GPS binary phase shift keying (BPSK) modulation. More complex techniques are already developed for tracking BOC signal, such as bump jump and BPSK-like.

SYSTEMS COMPARISONS

Precise positioning using GNSS technology is limited by the availability of satellite signals in specific locations. With GALILEO satellites added to the current GPS and GLONASS systems, users will have the possibility of tracking a large number of the total of 75 available satellites. This will give users the ability to access instantaneous precise positioning potentially everywhere in the world on a 24/7 basis, provided their receiver units can track all the GPS-GLONASS-GALILEO signals. Table 2 summarizes the characteristics of three GNSS systems.

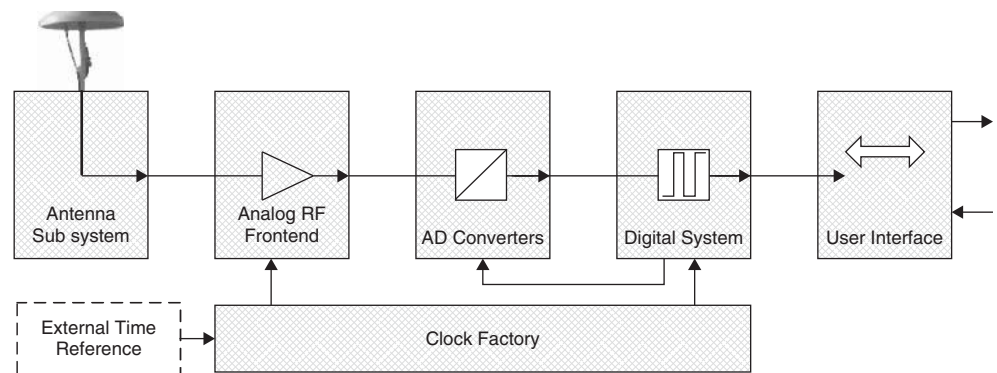

Figure 8: Hybrid GALILEO/GPS receiver concept

Table 2: Comparison of the GLONASS, GPS and GALILEO GNSS Systems

System	GLONASS	GPS	GALILEO
Nominal number of satellites	24	24	30
Design and operated by	Ministry of Defense of the Russian Federation (Military control)	DoD, USA (Military control)	ESA, (civil control) Multi-national (EU, China, India, etc.)
Operational satellites (April 2006)	12	30	1
Modernized and updated (expected full operation)	2008-2010	2004-2012	2008-2010
Orbital planes	3 (separated by 120°)	6 (separated by 60°)	3 (separated by 120°)
Satellites per orbital plane	8 (equally spaced)	4 (unequally spaced)	10 (equally spaced)
Orbital radius	25510 km	26560 km	29601 km
Inclination of orbital planes	64.8	55	56
Revolution period	11 h 16 min	11 h 58 min	14 h 5 min
Satellite Laser Ranging (SLR) reflectors	All satellites	Two satellites	All satellites
Signal separation technique	FDMA	CDMA	CDMA
Reference system	PZ-90	WGS-84	GTRF
Time reference	UTC (SU)	UTC (USNO)	GST

Systems Combination

The combined use of GPS and GLONASS were not taken into account in the original design of both systems. During the first few years of the 1990s, it had become clear that the GPS+GLONASS receiver might provide advantages over a solo (GPS-only or GLONASS-only) receiver provided interoperability issues could be resolved. However, GALILEO is in a more advantageous position with respect to GPS and GLONASS because many issues related to interoperability with existing navigation systems have been taken into consideration in initial design by forming the *GPS-Galileo Working Group*. The most important issues related to using the three systems in one GNSS receiver are:

- determination of transformation parameters among the three reference coordinate systems WGS-84, PZ-90, and GTRF;
- computing the time offset between GPS, GLONASS, and GALILEO system times;
- leap seconds in GLONASS and GALILEO;
- hardware biases among GPS, GALILEO, and GLONASS channels;

At present (2007), we can say that all of those issues have been resolved to a sufficient degree for practical needs for GPS+GLONASS and have already been taken into consideration for GPS+GLONASS+GALILEO.

The advantages of the combined GPS/GLONASS/GALILEO (GNSS) in the GNSS system are summarized in the following points:

- ability to work under environments with limited visibility of satellites;
- fast OTF ambiguity resolution;
- through GNSS receivers, elimination of periods of time when total number of current GPS satellites may not be sufficient for reliable positioning at a given location;
- more robust detection and exclusion of anomalies;
- improved estimation of tropospheric and ionospheric parameters;
- reduction of time required for collecting static data.

The use of GLONASS and GALILEO can provide additional advantages when working in high latitudes (Alaska, Canada, Scandinavia, etc.) because of the higher inclination of GLONASS orbits in comparison with GPS orbits. Due to the work at different frequencies, GLONASS is also more resistant to interference and jamming.

GALILEO and Military Systems

GALILEO is specifically designed for civil and commercial purposes, and it has some differences from the other two military systems GPS and GLONASS:

- increased accuracy, service guarantees, certification, and liability of the service operator and guaranteed accuracy to one meter for some applications

- traceability of past performance and operation transparency
- increased availability of signals in demanding environments.
- superior reliability because it has an integrity message which immediately informs the user of errors that may occur.
- Coverage of difficult areas such as Northern Europe.

Integrity Problems

Integrity is defined as “the ability of a system to provide timely warnings to users when the system should not be used for navigation.” GPS and GLONASS cannot provide such warnings. This can only be accomplished by augmentation systems such as DGPS reference networks. GALILEO, on the other hand, will be able to provide integrity information to its users, provided they are willing to pay for it. But integrity and availability requirements of GNSS have some limitations due to physics. The two major problems are power budget and masking. The power budget issue is due to economic and strategic reasons; the satellite signals are weak and consequently vulnerable to interference (Willigen 2003). The masking problem issue is due to use of 1-1.50GHz frequencies for navigation satellites, which cause buildings, foliage, and mountains to easily shield the signals.

REFERENCE SYSTEMS

Coordinate System

The definition of a reference coordinate system is crucial for the description of satellite motion, the modeling of observable and the interpretation of results. The reference coordinate system in satellite geodesy is global and geocentric by nature because satellite motion refers to the center of mass of the Earth (Seeber 2003; Hofmann-Wellenhof et al. 2001).

In satellite geodesy, two reference systems are required: (a) space-fixed, inertial reference system for the description of satellite motion and (b) Earth-fixed, terrestrial reference system for the positions of the observation stations and for the description of results from satellite geodesy.

Positioning using GNSS depends mainly on knowing the satellite coordinates. The position of the receiver is calculated with respect to the position of the satellite. If the range vector relation between satellite and receiver is considered, the coordinates of the satellite and receiver should be expressed in the same coordinate system.

In satellite geodesy, the two systems are used and the transformation parameters between the space-fixed and Earth-fixed coordinate systems are well known and used directly in the GNSS receiver and post-processing software to compute the position of the receivers in the Earth-fixed system.

The terrestrial reference system is defined by convention with three axes, where Z-axis coincides with the Earth's rotation axis as defined by the Conventional International Origin (CIO). The X-axis is associated with the mean Greenwich meridian, and the Y-axis is orthogonal to

Figure 9: ECEF coordinate system and ellipsoidal coordinates

both Z and X axes and it completes the right-handed coordinate system; see Figure 9. An example of the terrestrial reference system is the WGS84. GPS has used the WGS84 as a reference system (Leick 2003), and with WGS84, associated a geocentric equipotential ellipsoid of revolution. The basic idea in geodesy behind using the reference ellipsoids is that they fit the real shape of the Earth.

Another example of use of the terrestrial reference frame is the International Terrestrial Reference Frame (ITRF), which is established by Central Bureau of the International Earth Rotation Service (IERS). The ITRF is regularly updated and is more accurate than WGS84, but the difference between WGS84 and ITRF is now on the order of a few centimeters. This difference is mainly due to the difference between the reference stations used by each system when it is realized. Both systems are geocentric and the transformation parameters between them are regularly published by IERS.

The representation of position in geocentric Cartesian coordinates (X, Y, and Z) has less significance in navigation. Hence, the ellipsoidal representation (longitude, latitude, and height above the ellipsoid) are more commonly used for coordinate representation.

The relation between Cartesian coordinate (X, Y, Z) and ellipsoidal coordinates (φ , λ , and h) is expressed using the following formulas:

$$\begin{aligned} X &= (N + h) \cos \varphi \cos \lambda \\ Y &= (N + h) \cos \varphi \sin \lambda \\ Z &= \left(\frac{b^2}{a^2} N + h \right) \sin \varphi \end{aligned} \quad (2)$$

where N is the radius of curvature in prime vertical and is obtained by the following expression:

$$N = \frac{a^2}{\sqrt{a^2 \cos^2 \varphi + b^2 \sin^2 \varphi}}, \quad (3)$$

Here, a and b are the semi axes of the ellipsoid. The Cartesian coordinate of WGS84 is also called the ECEF (Earth Centered Earth-Fixed) coordinate system.

As mentioned above, the realization of the reference frame depends on the coordinates of ground reference stations. The Galileo Terrestrial Reference Frame (GTRF) is expected to be similar to ITRF, but will be based on the coordinates of the GALILEO ground stations. The differences between WGS84, ITRF, and the GTRF are expected to be on the order of a few centimeters. The two coordinate systems are compatible, and the accuracy obtained is good enough for most of the applications, including navigation. For highly precise measurements and for centimetric accuracy among the various systems, the transformation parameters are expected to be published by geodetic service providers such as IERS. GLONASS uses the PZ90 as a reference coordinate system, which is basically an ECEF system. The transformation parameters between PZ90 and WGS84 are published by IERS (Leick 2003).

It is interesting to note that there are many local best fitting (non-geocentric) ellipsoids used in the world. These ellipsoids are oriented and constrained by some astronomical measurements to be used as a local datum for better fitting a particular portion of the Earth. Examples of these include European datum 1950 (ED-50), which is the international ellipsoid 1924, and North American Datum 1927 (NAD-27), which is a Clarke ellipsoid. The center of the local ellipsoid doesn't coincide with true center of the Earth. Generally the distances or the vectors between the geocentric ellipsoid such as WGS84 and the local ellipsoids are well known to be used in the transformation between the local datum and the global geocentric one.

Time Reference Frame

There are many time reference systems used and they are based on various periodic processes, such as the Earth's

rotation. The major types of these systems are shown in Table 3. The conversion between time systems is accomplished with well-known formulas. In GNSS (e.g., GPS), the atomic time system serves as a reference instead of the dynamic time system itself.

The GLONASS satellite clock is moved according to UTC (SU). The Galileo System Time (GST) will be a continuous coordinate time scale steered toward the International Atomic Time (ITA) with an offset of less than 33 nanoseconds. The GST limits, expressed as a time offset relative to ITA, should be 50 nanoseconds for 95 percent of the time over any yearly time interval. The difference between GST and ITA, and between GST and UTC, shall be broadcast to the users using the signal-in-space of each GALILEO service. The GALILEO ground segment will monitor the offset of the GST with respect to the GPS system time and eventually broadcast the offset to users.

OBSERVATION TECHNIQUES

The basic concept of GNSS is to measure the signal traveling time between artificial satellite and receiver. By multiplying this time by the light velocity (c), we get the range between the satellite and the receiver (Hofmann-Wellenhof et al. 2001; Leick 2003); see Figure 10:

$$\text{Range} = c \cdot (t_R - t^S) = \Delta t_R^S \cdot c \quad (4)$$

The time or phase measurement performed by the receiver is based on comparison between the signal received by the receiver's antenna and the reference signal generated by the receiver. The two signals are affected by the clock's errors. Therefore, the range measured is not true and it is called pseudorange. Because the signal travels through the atmospheric layers, further noise should be modeled in order to compute the precise range.

Table 3: Time Systems (Hofmann-Wellenhof et al. 2001)

Periodic process	Time system	Abbreviation
Earth rotation	Universal Time	UT
Earth revolution	Terrestrial Dynamic Time	TDT
Atomic oscillation	International Atomic Time	ITA
	UT coordinated	UTC
	GPS Time	

Figure 10: Basic concept of range measurement

Code Pseudorange Measurements

Code correlation technique is used to measure the time difference between the received and generated replica code. The range can be formulated as follows:

$$R_R^S = c \cdot \left[(t_{R(GNSS)} - \delta_R) - (t^{S(GNSS)} - \delta^S) \right] \quad (5)$$

where δ^S is the satellite clock offset δ^S and δ_R is the receiver clock offset δ_R . A high stability atomic clock is generally used on board the satellite, so δ^S is small and could be modeled by a polynomial with the coefficients being transmitted in the navigation message. However, the receiver clock offset δ_R is large and is treated as an unknown to be estimated in the function:

$$R_R^S = c \cdot \Delta t_{GNSS} + c \cdot (\delta^S - \delta_R) = \rho + c \cdot \Delta \delta \quad (6)$$

where ρ is the true distance between satellite and receiver and its expressed by the vector in a reference geocentric coordinate system:

$$\rho = \sqrt{(X^S - X_R)^2 + (Y^S - Y_R)^2 + (Z^S - Z_R)^2} \quad (7)$$

Phase Pseudorange Measurements

Phase pseudo range is based on the measurements of phase difference between the received and generated signal $\Delta\varphi_R^S$ at the receiver. The received carrier is Doppler shifted due to the motion of satellite (Hofmann-Wellenhof et al. 2001).

In order to calculate the range using phase measurement, we have to add to $\Delta\varphi_R^S$ the number of cycles between the satellite and the receiver, which is an ambiguous value and is often called ambiguity (N). With consideration of the initial phase errors of the satellite and receiver due to their clocks, the mathematical model of phase pseudo range can be expressed by:

$$\Delta\varphi_R^S + N = -\frac{f}{c} \cdot \rho - f\delta^S + f\delta_R \quad (8)$$

If we rearrange the above equation and use $\Phi = -\Delta\varphi_R^S$ and $\Delta\delta = \delta^S - \delta_R$, it becomes similar to the code pseudorange equation, but with the additional the ambiguity value (N):

$$\lambda \cdot \Phi = \rho + c \cdot \Delta\delta + \lambda \cdot N \quad (9)$$

where λ is the wave length.

GNSS Observable Errors

The code and phase measurements are affected by noise and errors due to the propagation of signals through atmospheric layers and due to the noise measurements. These errors can be described briefly as below:

1. Satellite clock error: This can be modeled by the polynomial coefficients transmitted in the navigation message with respect to a reference time (e.g., GPS).

$$\delta^S = a_0 + a_1(t - t_0) + a_2(t - t_0)^2 \quad (10)$$

2. Orbital error: This can be eliminated by differential positioning. Precise orbits could be obtained in near real time via Internet from services centers such as International GNSS Service (IGS).
3. Ionospheric error: This error is modeled or eliminated by using the linear combination of two or multiple frequencies (Julien et al. 2004b). The relation between the ionospheric refraction has an effect on the future GNSS (L5, L2, and L1 for GPS; E5a, E5b, and E1 for GALILEO). We can write:

$$\begin{aligned} \lambda_1 \cdot \Phi_1 &= \rho + c \cdot \Delta\delta + \lambda_1 \cdot N - I_{L1} \\ \lambda_2 \cdot \Phi_2 &= \rho + c \cdot \Delta\delta + \lambda_2 \cdot N - \frac{f_1^2}{f_2^2} I_{L1} \\ \lambda_3 \cdot \Phi_3 &= \rho + c \cdot \Delta\delta + \lambda_3 \cdot N - \frac{f_1^2}{f_3^2} I_{L1} \end{aligned} \quad (11)$$

where, $\text{Ionosphere} = I_{L1}$

The effect of ionosphere on GNSS measurement is of special interest in solving the ambiguity number N (Liu and Lachapelle 2002). Having multiple frequencies can give more advantages for ionosphere models to estimate the first and second order effect of the ionosphere. Moreover, it allows more possibilities in the ambiguity-resolution process (Zhang et al. 2003). The ionosphere could also be modeled using the ionospheric coefficient transmitted by the navigation message.

4. The troposphere: This consists of two layers: the wet layer (up to 10 km above the surface of ground), and the dry layer from 10 to 40 km above the ground. The troposphere causes a delay in both the code and carrier observations. Because the troposphere is not frequency dependent, it cannot be canceled out by using dual frequency measurements, but it can, however, be successfully modeled. Tropospheric models depend on empirical models that consider all values of temperature, pressure, relative humidity, and mapping function. Examples of such models are the Hopfield and Saastamoninen models.
5. Receiver clock error: This is due to using a non-precise clock in the receiver (e.g., a quartz clock), which causes offset and drift in the receiver clock and GNSS reference time. This error is treated as unknown in the pseudorange computations. The clock receiver error could be eliminated in double difference equations as shown in the following section.
6. Multipath: This is caused by multiple reflections of the signals at the receiver or at the satellite due to multiple paths taken by the signal to arrive at the destination. The best way to reduce the multipath phenomenon is to choose a site away from a reflection surface (such as buildings, cars, trees, etc.), and by appropriate antenna design. Carrier phases are less affected by multipath propagation than code ranges, because multipath is frequency dependent. The multipath error could reach to a one meter level. The elimination of multipath is

possible by selecting an antenna that takes advantages of the signal polarization.

GNSS Positioning Techniques

There are two main types of positioning techniques in GNSS measurements: single-point positioning and differential positioning.

Single-Point Positioning

The basic concept of point position depends on the trilateration between the receiver and satellite. Range measurements from four satellites are needed to determine the four unknowns, X, Y, Z, and receiver clock offset ($\Delta\delta$). The analytical solution for receiver A and four satellites could be written as below:

$$\begin{aligned} R_A^1(t) &= \sqrt{(X^1(t) - X_A)^2 + (Y^1(t) - Y_A)^2 + (Z^1(t) - Z_A)^2} + c \cdot \Delta\delta \\ R_A^2(t) &= \sqrt{(X^2(t) - X_A)^2 + (Y^2(t) - Y_A)^2 + (Z^2(t) - Z_A)^2} + c \cdot \Delta\delta \\ R_A^3(t) &= \sqrt{(X^3(t) - X_A)^2 + (Y^3(t) - Y_A)^2 + (Z^3(t) - Z_A)^2} + c \cdot \Delta\delta \\ R_A^4(t) &= \sqrt{(X^4(t) - X_A)^2 + (Y^4(t) - Y_A)^2 + (Z^4(t) - Z_A)^2} + c \cdot \Delta\delta \end{aligned} \quad (12)$$

Generally, linearization in respect to the approximate position of the receiver is needed to resolve such a model, where the range R is measured by the receiver and the coordinate of the satellite is extracted from the navigation message. The unknowns in the above equation are X, Y, Z, and the clock error $\Delta\delta$. In the case of observing more than four satellites, the least square adjustment is performed to estimate the unknowns.

Hence, coordinates of the receiver and time offset could be obtained directly in real time with one epoch measurement. Geometric information could be obtained from the equation model as PDOP, which indicates the quality of the solution with respect to satellite geometry. Bad satellite distribution gives a large PDOP. Due to unmodeled errors in pseudo range such as ionosphere, troposphere, and orbital errors, the accuracy level of absolute positioning is within 10 meters.

Observable Difference

By considering all the systematic and random errors on the observation, we can write the math model for observable difference for code and phase measurements, respectively, as below:

$$R_A^1(t_0) = \rho_A^1(t_0) + \Delta\rho_A^1(t_0) + c\delta^1(t_0) - c\delta_A(t_0) + I_A + T_A + \varepsilon \quad (13)$$

$$\begin{aligned} \lambda\phi_A^1(t_0) &= \rho_A^1(t_0) + \Delta\rho_A^1(t_0) + \lambda N_A^1 + c\delta^1(t_0) \\ &\quad - c\delta_A(t_0) - I_A + T_A + \varepsilon \end{aligned} \quad (14)$$

Where $\Delta\rho_R^S$ is the orbital error, I is the ionosphere error, T is the troposphere error, and ε is the other types of noise and errors such as the ones due to multipath propagation.

Using two receivers A and B and satellite (1), we can perform Single Differences (SD). In SD the orbital error and satellite clock error are cancelled. By using two receivers and two satellites (1, 2), we can perform Double Differences (DD). In DD the clock receiver error is cancelled. By using two receivers, two satellites, and two consequent epochs, we can perform Triple Differences (TD). In TD the ambiguity is cancelled.

$$\begin{aligned} SD &= \lambda\phi_{AB}^1(t) = \lambda\phi_B^1(t) - \lambda\phi_A^1(t) = \rho_{AB}^1(t) + \lambda N_{AB}^1 - c\delta_{AB}(t_0) \\ DD &= \phi_{AB}^{12}(t) = \frac{1}{\lambda} \rho_{AB}^{12}(t) + N_{AB}^{12} \\ TD &= \phi_{AB}^{12}(t_{12}) = \frac{1}{\lambda} \rho_{AB}^{12}(t_{12}) \end{aligned} \quad (15)$$

As we see, most of systematic errors are cancelled or reduced by using the observable differences. Consequently, the accuracy of position computation will be improved after eliminating or reducing these biases. The solution obtained in DD with ambiguity can provide precision to the centimetric level.

Differential Position

There is increased interest in differential positioning due to the numerous advantages of wireless communications and networks. Most of errors that affect GNSS are common between the receivers, which observe the same set of satellites (Leick 2003; Hofmann-Wellenhof et al. 2001). Thus, making differential measurement between two or more receivers could cause most of these errors to be cancelled.

The basic concept of differential position is the calculation of position correction or range correction at the reference receiver and then sending this correction to the other receiver via radio link. In this way, most of the errors are cancelled; see Figure 11. The transmitted correction could be of several types: the position or pseudo range correction, the carrier smoothed pseudo range correction, and the carrier phase correction. The mathematical model of

Figure 11: Differential correction

DGNSS could be written as shown below. Two receivers are used, where receiver A is installed at known reference station and B is rover/moving receiver. Pseudo range at A is given by:

$$R_A^1(t_0) = \rho_A^1(t_0) + \Delta\rho_A^1(t_0) + c\delta^1(t_0) - c\delta_A(t_0) \quad (16)$$

$$\begin{aligned} PRC^1(t_0) &= -R_A^1(t_0) + \rho_A^1(t_0) \\ &= -\Delta\rho_A^1(t_0) - c\delta^1(t_0) + c\delta_A(t_0) \end{aligned} \quad (17)$$

We have to add the range rate correction for an arbitrary epoch (t).

$$PRC^1(t) = PRC^1(t_0) + RRC^1(t_0)(t - t_0) \quad (18)$$

where $(t - t_0)$, is called the latency due to transmission time between the reference and the rover receiver. The pseudo range at receiver B can be written as:

$$R_B^1(t) = \rho_B^1(t) + \Delta\rho_B^1(t) + c\delta^1(t) - c\delta_B(t) \quad (19)$$

By adding the pseudo range from reference station, we obtain:

$$\begin{aligned} R_B^1(t)_{corr} &= R_B^1(t) + PRC^1(t) \\ &= \rho_B^1(t) + (\Delta\rho_B^1(t) - \Delta\rho_A^1(t)) - (c\delta_B(t) - c\delta_A(t)) \end{aligned} \quad (20)$$

$$R_B^1(t)_{corr} = \rho_B^1(t) - c\Delta\delta_{AB}(t) \quad (21)$$

As we see, the orbital error is cancelled and the satellite clock error is eliminated. We can also transmit the phase correction to the rover receiver. In this case, we have to add another unknown; the ambiguity N, to the equations. If the same procedure as above is applied, the phase range correction between the reference and the rover receiver will be given by:

$$\lambda\phi_B^1(t)_{corr} = \rho_B^1(t) + \lambda\Delta N_{AB}^1 - c\Delta\delta_{AB}(t) \quad (22)$$

DGNSS with phase range correction is used for most precision Real-Time Kinematics (RTK). But the ambiguity should be resolved or fixed by using the On The Fly (OTF) techniques. In phase measurement technique, the precision obtained will be at the centimeter level. Modeling the ionosphere and troposphere will eliminate or reduce the errors in DGNSS. This method gives more possibilities of obtaining high accuracy in point positioning using one receiver.

Wide Area Differential GNSS (WADGNSS)

WADGNSS is a scheme that would allow the user to perform differential positioning and obtain reliable position with high accuracy in real time over a sizeable region. WADGNSS consists of a master control station and a

number of local or global monitor stations and communication links. The monitor stations gather the data from GNSS satellite, and then send them to the master control station. The master control estimates the ionosphere parameter, troposphere parameters, satellite ephemerides, and clock errors. All these corrections are transmitted to the user via the Internet, wireless communications, or satellite communications.

Depending on the distribution of the reference monitor stations and the accuracy of error modeling and communication capabilities, the accuracy of the rover receiver could be in the range of 1 to 3m. Centimetric accuracy could be achieved by receiving phase correction and ambiguity fixing such as the RTK and Virtual Reference Station (VRS). Programs are already developed to send the GNSS corrections to the user to obtain higher accuracy. As mentioned above, transmitting a phase correction with error models for ambiguity fixing will give centimetric precision for the rover receiver. Wireless communications and the Internet have offered us new possibilities to apply real-time positioning to obtain centimetric precision using one receiver (Leick 2003).

The mathematical model of WADGNSS can be written by adding all the errors affecting the satellite signals as follows:

$$\begin{aligned} \lambda\phi_A^1(t_0) &= \rho_A^1(t_0) + \Delta\rho_A^1(t_0) + \lambda N_A^1 + c\delta^1(t_0) \\ &\quad - c\delta_A(t_0) - I_A + T_A \end{aligned} \quad (23)$$

The most common Satellite-Based Augmentation System (SBAS) programs used in WADGNSS are WAAS, EGNOS, and MSAS (WAAS 2002; GALILEO 2003)

Wide Area Augmentation System (WAAS)

Wide Area Augmentation System (WAAS) is a new augmentation to the United States Department of Defense's (DoD) Global Positioning System (GPS) that is designed to enhance the integrity and accuracy of the basic GPS capability.

The WAAS uses geo-stationary satellites to receive data measured from many ground stations, and it sends information to GPS users for position correction. Because WAAS satellites are of the geo-stationary type, the Doppler frequency caused by their motion is very small. Thus, the signal transmitted by the WAAS can be used to calibrate the sampling frequency in a GPS receiver. The WAAS signal frequency is 1575.42 MHz. The WAAS services will be available on both L1 and L5.

GNSS-1: EGNOS

The European Geostationary Navigation Overlay Service (EGNOS) is being developed by European Space Agency (ESA) for the Safety of Air Navigation (Eurocontrol). EGNOS will complement the GNSS systems. It consists of three transponders installed in geostationary satellites and a ground network of 34 positioning stations and four control centers, all interconnected. EGNOS, like WAAS, broadcasts the differential corrections to the GNSS users through geo-stationary satellites in the European region and beyond.

Figure 12: Footprint of global differential corrections services of GNSS: U.S. (WAAS), E. U. (EGNOS), and the Japanese (MSAS)

MSAS

Like the WAAS and EGNOS, the Japanese MTSAT Satellite-Based Augmentation System (MSAS) is used to send the differential correction for GNSS users; see Figure 12.

WIRELESS SYSTEMS AND GNSS APPLICATIONS

Wireless communication and network systems offer a new line of GNSS applications by sending the differential position corrections to the GNSS users. Other applications forced GNSS to be integrated with wireless communications, such as the third generation (3G) wireless mobile networks for RTK network (VRS). Other applications are also integrated with GIS and wireless communications such as LBS applications (emergency call and AVL).

On the other hand, GNSS is used in digital communication networks to meet the requirement for precision timing synchronization and position information. Increased timing accuracy provides overall improvement in system performance in terms of quality and efficiency. The telecommunications infrastructure uses the GNSS signal as an integral and basic part of the system.

GNSS could improve the communication capacity of networks, especially for the UMTS third-generation using Code Division Multiple Access (CDMA) techniques. A precise time-synchronization of the different base stations (the UMTS emitter-antennas) can significantly increase the traffic capability of the system.

Timing and Synchronization

Characteristics of good telecommunications service include being continuous and transmitting information (transmission packet) with a low error rate and noise. Such a good performance can be accomplished by using precise timing and efficient synchronization mechanisms. GNSS technology is frequently used for this purpose because the GNSS chip (actually GPS chip), has a low cost and the timing information can be obtained easily from one satellite with high stability characteristics. All the clocks installed in the nodes of wireless networks should match or trace the Synchronization Standard established by The American National Standards Institute (ANSI) for performance of a primary reference source as 1×10^{-11} . The GNSS chip is relatively inexpensive. Naturally

interference or jamming of GNSS signal could affect the timing synchronization in the telecommunications network, which consequently degrades telecommunications services (Omar and Rizos 2003).

GNSS and Wireless Networks

There are many types of wireless networks, cellular networks, Wireless Local Area Networks (WLAN), and multi-hop wireless networks for providing Internet services and control systems (Nicolopolitidis et al. 2003). GNSS technology is not widely used in wireless networks for positioning of information because most protocols and algorithms in wireless networks do not use position information in their operations, even though it is very advantageous for many applications such as providing Internet services for mobile users (cars, trains, etc.) (Jain et al. 2001).

Geographical Routing Algorithm (GRA) is generally used in wireless networks for packet destinations between nodes when good knowledge of network topology is not available. Using GNSS for location information and time synchronization will help to optimize packets' routes to the destination between the nodes in the ad hoc wireless network and increase the efficiency of services by selecting the closest nodes (shortest path).

RTK Networks

The RTK network concept is similar to the Wide Area DGNSS, but the reference stations are generally distributed over a regional area and the network control center is responsible for transmitting the phase measurement correction to the GNSS user (rover receiver). Mobile wireless networks (GSM, GPRS, EDGE, CDMA2000, and UMTS) are generally used in this type of application due to the need for duplex communication where the rover receiver should initially send the approximate position to the network processing center. The network processing center computes VRS observations and sends them to the user (Euler 2005); see Figure 13. This scheme is commonly used in many systems worldwide due to its economic and precision advantages. The number of reference stations in the single RTK approach is 30 stations in $10,000 \text{ km}^2$; however, through the use of the RTK network, the reference stations could be reduced to five stations in the $10,000 \text{ km}^2$ area.

Location Based Service (LBS)

Location Based Services (LBSs) provide personalized services to subscribers based on their current positions. LBSs employ accurate, real-time positioning to connect users to nearby points of interest. LBS advises them of current conditions such as traffic and weather, or provides routing and tracking information, all via wireless devices.

The location of the caller is generally determined by various position determination techniques. These include Cell-ID, Enhanced Observed Time Difference (E-OTD), Observed Time Difference of Arrival (OTDOA), Wireless Assisted GNSS (A-GNSS) and hybrid technologies (combining A-GNSS with other standard technologies).

Positioning techniques based on the use of a GNSS or cellular network infrastructure itself is growing rapidly

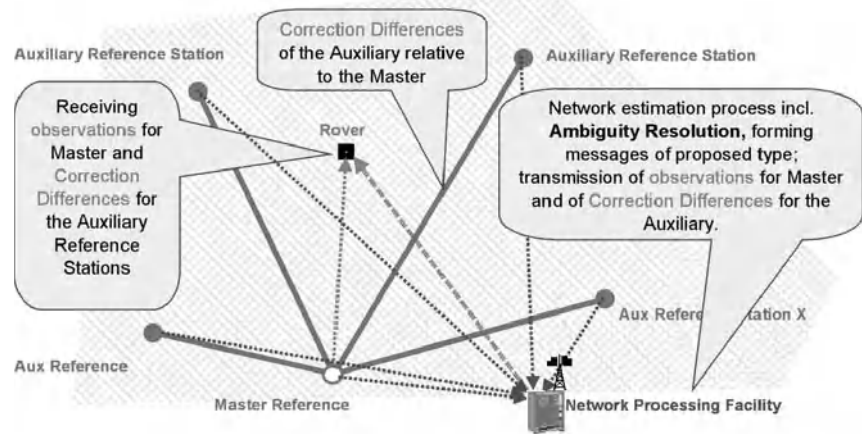

Figure 13: RTK network (Euler 2005)

in the mobile-telephone community. There are many LBS projects that already based on the combination of wireless communications (e.g., GPRS), satellite navigation (GNSS), and geographic information systems (GIS). Some of these projects are based on the Mobile Client / Server architecture (Lohnert et al., 2001).

GNSS receiver is mainly responsible for position determination, and precise time and velocity in the coordinate reference system, and then saving these data in the National Marine Electronics Association (NMEA) format to be transmitted to the control center via wireless communication or downloaded directly via serial ports such as RS-232, USB 2.0, etc.

LBS Applications

The LBS applications and needs can be divided into four main areas:

1. **Information and navigation services:** These services provide data directly to end-users, in particular destination location and criteria for trip optimization. Automobile manufacturers are offering moving map

displays guided by navigation GNSS (currently GPS) receivers as an option on new vehicles. In some cases, the displays can be removed and taken into the home to plan a trip. Many rental car companies have GPS-equipped vehicles that give directions to drivers on display screens and through synthesized voice instructions. Also, some companies (such as Navtique and Tele Atlas) are specialized in preparing the maps and voice guidance for navigation systems used in vehicles.

2. **Emergency assistance:** This type of service provides the location of mobile users in case of distress and need for assistance such as: E-911 in the United States and E-112 in Europe. GIS capabilities are essential in such services.
3. **Tracking services:** In general, an AVL system consists of a GNSS receiver integrated with a GSM/GPRS module mounted on the vehicle, a communication link between the vehicle and the dispatcher, and PC-based tracking software for dispatching (Figure 14) (Al-Bayari and Sadoun 2005). Vehicle tracking is one of the fastest-growing GNSS applications today. GPS-equipped fleet vehicles, public transportation systems,

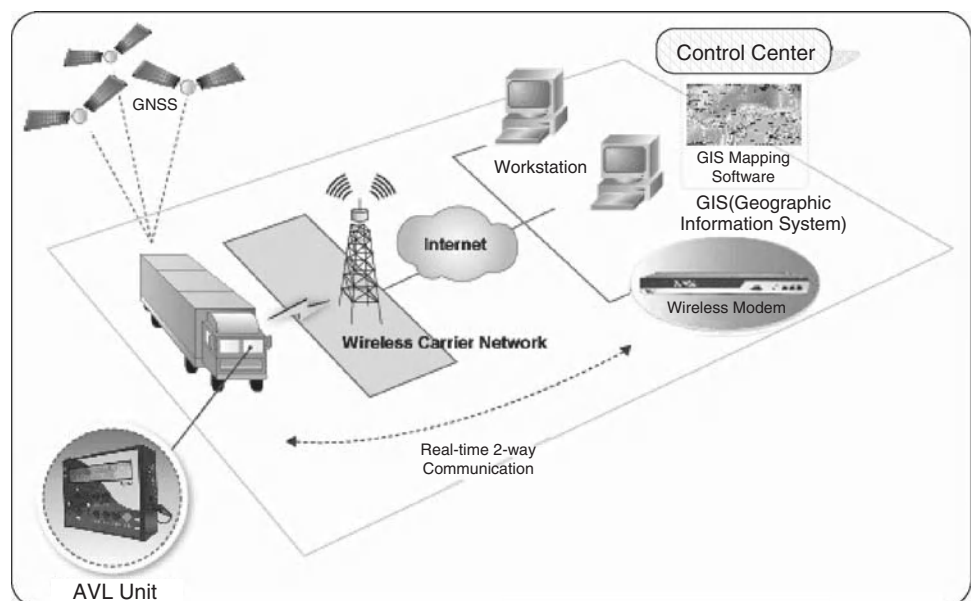

Figure 14: AVL system components

delivery trucks, and courier services use GNSS receivers to monitor their locations at all times. The principal benefit of AVL system in fleet management is the opportunity for increasing and improving the efficiency use of human and environmental resources in effective manners. Transportation infrastructure represents one of the largest and most critical investments by any country. Movement of people and goods is vital to every aspect of the country's economy. GIS- and AVL-based asset management for road and railway transportation systems can greatly improve the efficiency of operations (optimizing services, costs, and fleet usage), while at the same time, can make significant contributions to safety, including responses to natural and man-made disasters.

4. **Network related services:** Here knowledge of user's position improves communication services. Location can be achieved by integrating a GNSS receiver in the mobile phone (handheld solution) or by using the communication network itself.

LBS techniques based on GSM, GPRS, and WCDMA (Wideband Code Division Multiple Access) networks alone don't offer high accuracy. Moreover, GNSS alone is insufficient to maintain continuous positioning due to the inevitable difficulties caused by obstacles. When GNSS signals are blocked or lost, the precision of positioning will be minimized to unacceptable level. Hence, it is necessary to improve the accuracy and reliability of GNSS position.

The accuracy of position determination could be improved by Differential GNSS (DGNSS), Dead Reckoning (DR), indoor GNSS, or integrating GNSS with the above mentioned schemes such as Cell-ID (Hybrid location technology).

NMEA Format

The National Marine Electronics Association is a U.S. standards body that defines message structure, content, and protocols to allow electronic equipment installed in ships and boats to communicate with each other. GPS receivers can be configured to output various types of messages in the "NMEA format." Most computer programs that provide real-time position information understand and expect data to be in NMEA format. This data includes the complete PVT (position, velocity, time) solution computed by the GPS receiver. The idea of NMEA is to send a line of data called a sentence that is totally self-contained and independent from other sentences. There are standard sentences for each device category and there is also the ability to define proprietary sentences for use by the individual company. All of the standard sentences have a two-letter prefix that defines the device that uses that sentence type. For GPS receivers the prefix is GP, which is followed by a three-letter sequence that defines the sentence contents such as GP-RMC (GPS- Recommended Minimum Specific GPS Data). In addition, NMEA permits hardware manufacturers to define their own proprietary sentences for whatever purpose they see fit. All proprietary sentences begin with the letter P and are followed with three letters that identify the manufacturer controlling that sentence. For example a Garmin sentence would start with PGRM and Magellan would begin with PMGN. There are various versions of NMEA format (NMEA 0180, 0182, 0183).

There are many sentences in the NMEA-0183 Standard Input/Output messages protocol for all kinds of devices that may be used in a marine environment (Baddeley 2003). Some of the ones with applicability to GPS receivers are listed below: (all message start with GP.) The most important NMEA sentences include the GGA, which

Table 4: GPRMC Description

Name	Example	Units	Description
Message ID	\$GPRMC		RMC protocol header
UTC (time)	101841	hhmmss.sss	Universal Time Coordinate
Status	A		A=data valid or V data not valid
Latitude	3216.4838	ddmm.mmmm	
N/S Indicator	N		N=north or S=south
Longitude	03613.9412	dddmm.mmmm	
E/W	E		E=east or W=west
Speed Over Ground	001.1	knots	
Course Over Ground	015.7	degrees	True
Date	070203	ddmmyy	
Magnetic Variation		degrees	E=east or W=west
Checksum	*10		
			End of message termination

provides the current Fix data; the RMC, which provides the minimum GPS sentences information; and the GSA, which provides the Satellite status data.

- GGA Global positioning system fixed data
- GLL Geographic position – latitude/longitude
- GSA GNSS DOP and active satellites
- GSV GNSS satellites in view
- RMC Recommended minimum specific GNSS data
- VTG Course over ground and ground speed

Each sentence has a specific record description; see Table 4. The following format is a RMC data (*RMC – Recommended Minimum Specific GNSS Data*):

```
GPRMC,101841,A,3216.4838,N,03613.9412,E,001.1,015.7,070203,003.5,E,A*1D,33843
```

CONCLUSION

Global Navigation Satellite Systems (GNSS) technology has become vital to many applications that range from city planning, engineering and zoning, to military applications. It has been widely accepted by all governments and organizations worldwide. That is why very soon we expect to have at least three GNSS systems: the USA GPS, European GALILEO, and the Russian GLONASS systems. There is a multibillion dollar investment in this field and intensive worldwide research activities. The impressive progress in wireless communications and networks has played a great role in increasing interest in GNSS and providing enabling methodologies and mechanisms. It is expected that all 3G and future generations of cellular phones will be equipped with GNSS chips.

GNSS technology dominates outdoor navigation, which provides accuracy to from the range of few meters to 10 m in single point positioning technique or from sub-meter to a few meter level in differential GNSS technique (DGNSS). Various techniques have recently been developed for indoor positioning. They offer either absolute or relative positioning capabilities with acceptable precision (Hightower and Borriello 2001). Combining these technologies with GNSS allows us to provide a more reliable and robust location solution. The most common implementation of hybrid technology for GSM, GPRS, and WCDMA is to combine A-GNSS with Cell-ID.

GLOSSARY

Ambiguity: Integer bias term; the initial bias in a carrier-phase observation of an arbitrary number of cycles. The unknown number of whole wavelengths of the carrier signal between a satellite and receiver at the beginning of tracking.

Antispoofing (AS): This is the mechanism of encrypting the P-code by W-code to produce a new Y-code, to prevent replication by potentially hostile forces.

Automatic Vehicle Location (AVL): This is the scheme that uses a navigation system, such as GPS, to find out a vehicle's position.

Differential GPS (DGPS): A technique to minimize error in GPS-derived positions by using extra data from a reference GPS receiver at a known location, to enhance the accuracy of measurements made by other GPS receivers within the same general geographic area.

Doppler Shift: The phenomenon caused when the signal transmitter and receiver are moving relative to one another. In such a situation, the frequency of the received signal will not be the same as that of the source. When the signal transmitter and receiver are moving toward each other, the frequency of the received signal is higher than that of the source, and when they are moving away from each other, the frequency becomes lower.

Earth Centered, Earth Fixed (ECEF): This is a Cartesian coordinate system that starts at the Earth's center of mass. The Z-axis is associated with the Earth's mean spin axis. The X-axis is aligned with the zero Meridian. The Y-axis is 90 degrees west of the X-axis, making up a right-handed coordinate system.

Ellipsoid: A mathematical demonstration of the Earth as an ellipse that is turned around its minor axis. This is usually used as a reference surface for geodetic surveying and navigation applications.

Geostationary Satellites: Types of popular satellite systems that are usually launched at an orbit of about 35,863 km from the surface of the Earth at the equator. At such orbit the rotational period of the Earth is equal to that of the satellite.

GNSS (Global Navigation Satellite System): A global navigation satellite system, which is made up a network of satellites that transmit ranging signals used for positioning and navigation anywhere around the globe as well as in the air or at sea. Examples of such systems include the famous and oldest U.S. Global Positioning System (GPS), the Russian GLObal NAVigation Satellite System (GLONASS), and the upcoming European GALILEO system.

Location Based Services (LBS): A term used for the technique that establishes the location of caller by using various positioning schemes.

Ionosphere: The portion of the Earth's external atmosphere where ionization caused by incoming solar radiation changes the propagation of radio waves. The ionosphere extends from about 70 kilometers to 1000 kilometers above the Earth's surface.

On-the-Fly (OTF): A term used to characterize a scheme that resolves differential carrier-phase integer ambiguities without the need to have a GPS receiver stationary at any time

Pseudorange: This refers to the calculated range from the GNSS receiver to the satellite found by taking the difference between the measured satellite transmit time and the receiver time of measurement, and multiplying by the speed of light.

Real-Time Kinematic (RTK): This refers to a DGNSS process in which carrier-phase corrections are sent in real-time from a reference receiver at a known location to one or more remote rover/mobile receivers.

Satellite-Based Augmentation System (SBAS): A geo-stationary satellite system that enhances the accuracy, integrity, and availability of the basic GNSS

signals. Examples of such systems include WAAS, EGNOS, and MSAS.

INTRODUCTION

Overview

During the last few years, wireless technology has permeated every aspect of our lives. The fob on a keychain (to open the car remotely), wireless mice/keyboards, and personal digital assistants (PDAs) synching with workstations are just a few examples. This proliferation of wireless devices was the result of the Federal Communications Commission (FCC) decision to open the industrial, scientific, and medical (ISM) band to the public. Wireless local area networks (WLANs) were among the domains that benefited from this release. The release from licensing motivated many companies and research labs to develop and implement wireless local area network (LAN) solutions.

This disorganized and parallel effort resulted in the emergence of proprietary solutions that do not interoperate among one another. Lack of interoperability results in limited scope of acceptance because buyers of the technology from one vendor will have to either remain with that vendor or go through the pains of trying to work out a solution using different technologies. The IEEE 802.11 Working Group was formed to create a universal standard that can be followed by different vendors.

The first standard was released in 1997 and supported data rates up to 2 Mbps (IEEE 1997); the specification defined both the physical and the medium access control layers. Other standards followed that addressed different requirements and provided higher data rates. These included the 802.11b, 802.11a, and 802.11g with higher data rates; the 802.11e for quality of service (QoS) support; the 802.11i for security, and others.

Parallel to the 802.11 effort, the European Telecommunications Standards Institute (ETSI) was working on the high performance radio LAN (HIPERLAN) project.

Unlike the 802.11, which tried to use available technology, the HIPERLAN was built from scratch; the development of HIPERLAN was not driven by existing technologies and regulations. Rather, it was developed only to meet a defined set of goals. The HIPERLAN type 1 supports data rates up to 25 Mbps. HIPERLAN types 2, 3, and 4 specify standards for wireless asynchronous transfer mode (ATM) supporting data as well as QoS applications.

Applications of WLANs

Like their wired counterparts, wireless LANs can be used to provide connectivity within a limited geographic area. Mobility—the ability to move around while remaining connected—is a great feature of wireless LANs. In a working environment in which staff members need to be mobile yet constantly connected to the network, WLANs are inevitable. Doctors and nurses accessing patients' data instantly, work coordination among members at different locations of the premises, and students' access to their accounts and class information around the campus are just a few examples of how easy and convenient life can be with mobility support. An implication of mobility is outdoors connectivity. A wired network stops where your sockets and phone lines stop. A wireless LAN, on the other hand, can provide you with connectivity while you are drinking coffee at a street corner café.

A less obvious advantage of WLANs is their ability to address feasibility of running wires. Wireless LANs can be used to connect two wired LANs in different buildings. This might be the only way to provide connectivity, because accessing a public property (e.g., across the street) is not always possible. In this scenario, two bridges or switches can communicate wirelessly with each other in order to connect the two LAN segments. Even within the same building, a wired network may be unfeasible

or impossible. In addition, the infrastructure-less ad hoc topology of WLANs can be used in places where fast deployment is needed (e.g., for relief and recovery teams in disaster areas). Ad hoc networks allow a group of nodes to communicate with one another in a distributed, peer-to-peer manner, without prior arrangement. They can also be used for settings in which temporary connectivity is needed (e.g., a meeting of people who need to exchange files and presentations).

Yet another advantage of wireless LANs is their cost-effectiveness. A major part of a traditional wired LAN's installation is a result of cabling, the implications of running conduits around, and so forth. Getting rid of cabling entails the seamless additions, deletions, and modifications of the topology at no cost whatsoever. Additionally, costs needed to run and maintain wires are eliminated in a WLAN.

Chapter Organization

The remainder of the chapter is organized as follows. The following section, "802.11 MAC," discusses the possible topologies of 802.11 MAC as well as the MAC protocol description. The possible physical layers, along with needed background information, are provided in the section entitled "802.11 Physical Layer." The section entitled "HIPERLANs" discusses HIPERLAN types 1 and 2. Security and QoS support in 802.11 are described in the next two sections, "WLANs Security" and "QoS Support: 802.11e." The chapter concludes with a brief description of some advanced topics in wireless networks.

802.11 MAC

Possible Topologies

Wireless LANs can be either infrastructure based or ad hoc. The latter LANs have no pre-existing infrastructure or centralized management to support the mobile nodes. They consist of wireless nodes that can freely and dynamically self-organize into arbitrary and temporary network topologies. On the other hand, an infrastructure WLAN is based on central control (e.g., by using an access point). This section will describe both schemes. The following classification of the different organizations of a wireless LAN is based on the concept of a service set. A service set is nothing but a logical grouping of nodes. A node belongs to only one service set. In this context, *belongs* means that it listens only to transmissions from a particular service set.

Basic Service Set

The basic service set (BSS) resembles the basic building block in the 802.11 architecture. Nodes in a BSS communicate with one another through an access point (AP). An access point is responsible for coordinating communication among the nodes by receiving a node's transmission and forwarding it to the respective receiver. The access point is analogous to a base station in a cellular network, and a BSS is analogous to a cell in a cellular network. The coverage area of a BSS is called a basic service area (BSA). Figure 1 illustrates the concept of a BSS (Crow et al. 1997a).

Figure 1: A BSS organization of a wireless LAN

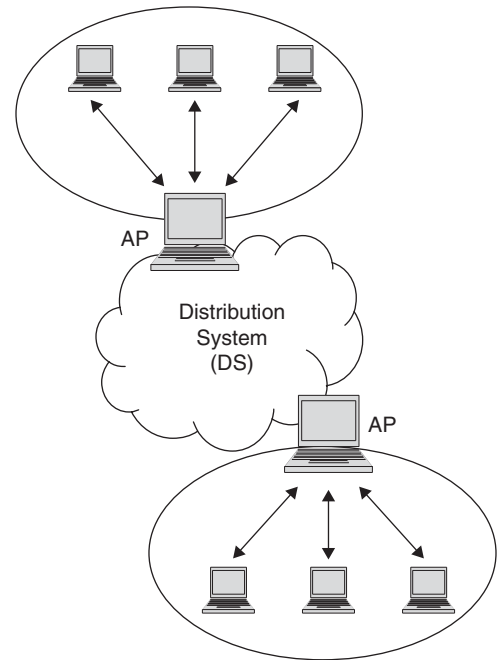

Figure 2: The ESS organization of a wireless LAN

Extended Service Set

Figure 2 shows how multiple BSSs can be connected to one another by connecting their APs to a distribution system (DS), thereby forming what is called an extended service set (ESS). Although the APs can connect to the DS via a wired or wireless connection, the connection usually is wired. The DS resembles the backbone of the ESS and is responsible for communicating MAC segments from one BSS to another or from one BSS to an external wired network (Crow et al. 1997a).

Independent Basic Service Set

The BSS and its extension (through an ESS) both resemble an infrastructure-based organization. The independent basic service set (IBSS), on the other hand, resembles the infrastructure-less ad hoc arrangement (see Figure 3). In an IBSS, stations communicate in a peer-to-peer fashion in which no AP or any other intermediary is needed. At least two stations are needed to form an IBSS.

Access Modes: DCF

The distributed coordination function (DCF) is the basic access mode of the 802.11 standard. It is based on

Figure 3: The IBSS (ad hoc) organization of a wireless LAN

the carrier sense multiple access with collision avoidance (CSMA/CA) scheme. The DCF is a contention-based protocol: stations have to compete every time they want to access the channel. Before delving into the details of the protocol, an important question that comes to mind is why a specialized MAC is needed. Why can't we simply adopt a wired MAC protocol? This section begins with an answer to this question, including the issues that arise in a wireless communication context.

Why Wired-Network Channel Access Does Not Work

Carrier sense multiple access with collision detection (CSMA/CD) is used in the IEEE 802.3 Ethernet standard. The basic idea is that the sender senses the medium (a cable to which all the nodes in the Ethernet segment are attached); if the medium is busy, the sender backs off and tries again later. If the channel is idle, on the other hand, the sender sends and keeps listening to the channel. If it hears a collision at any point during its transmission, the sender stops transmitting and sends a jamming signal.

The basic assumption in the CSMA/CD protocol is that a collision taking place at the receiver can be detected at the sender. This is true because the signal strength is basically the same throughout the medium. However, this assumption does not hold anymore for the wireless medium because the signal strength decreases with the square of

the distance from the transmitter. Thus, an event may take place and not be detected by the transmitter. The hidden and exposed terminal problems discussed next stem from this fact. In addition, a wireless node does not have the ability to transmit and receive at the same time because its own transmission would swamp any other signal in the vicinity (Nicopolitidis et al. 2003; Schiller 2002).

Figure 4 shows three stations: A, B, and C. The transmission range of A reaches B but not C. Similarly, the transmission range of C reaches B but not A. A's detection range (the range within which A can sense the medium) does not include C. C's detection range does not include A either.

A, willing to transmit to B, senses the channel and finds it idle. As a result, it starts transmitting. Meanwhile, C becomes interested in sending data to B. Sensing an idle channel, C does not detect the ongoing transmission between A and B because it is out of its range. C also starts transmitting to B, which results in a collision at B that is not detected by either A or C. This problem, in which two nodes are out of reach of each other but within the reach of a third node, is referred to as the hidden terminal problem (or hidden node problem).

Another problem associated with the inability to detect collisions is the exposed terminal problem, which is illustrated in Figure 5. In this case, B is transmitting to A. C, willing to send to D, senses the channel and finds it busy. If C transmits, its transmission will not interfere with the ongoing transmission between B and A, because A is outside its range. C's transmission, even though it would collide with B, would not collide with A because the signal would be too weak to cause a collision. Thus, C postpones its transmission even though it should not. In this case, C is *exposed* to B.

Consider the situation in which node A is closer to node C than it is to node B, as shown in Figure 6. In this case, even though both A and B can reach C, the signal power of A's transmission is much higher than that of B's transmission. As a result, C cannot hear B's transmission.

Figure 4: The hidden terminal problem

Note: C is outside the transmission and detection range of A; similarly, A is outside the transmission and detection range of C

Figure 5: The exposed terminal problem

Note: C is out of A's range but is within B's range. Hence, C postpones transmitting to D even though it should not. Although it would collide with B, it would not collide with A

Figure 6: The near-far effect

To circumvent this problem, B has to compensate for the difference in distance by transmitting at higher signal strength. This is the near-far effect, and it contrasts with wired networks, in which nodes generally receive the same signal strength.

Carrier Sense Multiple Access with Collision Avoidance

The wireless medium imposes its own requirements on the design of a MAC protocol. The main issue to be dealt with is the inability to detect collisions; therefore, collisions have to be eliminated or at least minimized. The carrier sense multiple access with collision avoidance was created for just this purpose. Using CSMA/CA, nodes perform two types of carrier sensing: physical carrier sensing and virtual carrier sensing, which refer to sensing at the physical and MAC layers, respectively. The channel is considered busy if either the physical or the virtual carrier sensing results in a busy channel indication. Physical carrier sensing is done by monitoring the medium for any ongoing transmissions, which involves looking at the strength of any received signal. Virtual carrier sensing can be explored by reviewing how the hidden terminal problem is being handled.

In Figure 7, which has the same scenario as Figure 4, when node A decides to send to node B, it first sends a request-to-send (RTS) control packet. All nodes within the range of A overhear the RTS packet and postpone their attempt to transmit. When B receives the RTS packet, it sends back a clear-to-send (CTS) packet. All nodes in the range of B will defer any attempt to transmit. Node C is not going to transmit to B because it hears the CTS packet. This procedure is also known as the four-way handshake.

Even though the RTS/CTS exchange mitigates the hidden terminal problem, it does not solve it entirely. For example, A and C may both transmit an RTS packet at the same time. Another possibility is that when B sends the CTS, C sends an RTS resulting in a collision of both control packets at C. Node C, not hearing the CTS sent to A nor a

CTS for its own RTS, retransmits the RTS, which collides with A's packet.

Collisions involving the RTS/CTS control packets carry small penalties when compared with data packets' collisions. This is readily apparent from the sizes of the RTS and CTS packets (20 bytes and 16 bytes, respectively) in contrast to the maximum data packet size, which is 2346 bytes. Thus, the RTS/CTS exchange provides better overall performance.

The basic idea behind virtual carrier sensing involves announcing for how long a node will occupy the channel so that all nodes hearing the announcement will defer their transmissions. To achieve this, every packet (be it a data packet, RTS, or CTS) carries a duration field that indicates the amount of time the channel will be needed after the current packet transmission is done. This period includes the time to transmit the RTS, CTS, data packet, and returning acknowledgment (ACK). Every node maintains what is called a network allocation vector (NAV). Nodes adjust the values of their vectors as they overhear packet transmissions. A node attempts to check the channel status (whether idle or not) only when the duration in the NAV elapses.

Priority in accessing the wireless channel is provided through the use of inter-frame spacing (IFS), which is the duration of time that has to pass before an attempt is made to access the channel. Three IFSs are defined in the protocol; in increasing order of importance, these are the distributed coordination function IFS (DIFS), point coordination function IFS (PIFS), and short IFS (SIFS). The SIFS is the shortest amount of time and hence the highest priority, followed by the PIFS (used by the PCF), and the DIFS (the time delay used by DCF frames).

Figure 8 shows how a frame transmission takes place along with the NAV table's adjustments at other nodes (those that are not involved in the current transmission). Prior to sensing the channel, a node has to wait the length of a DIFS duration. After that, if the channel is idle, the node sends an RTS. The duration field is set to include the time for the CTS, the data packet, the ACK, and

Figure 7: The RTS/CTS control packet exchange

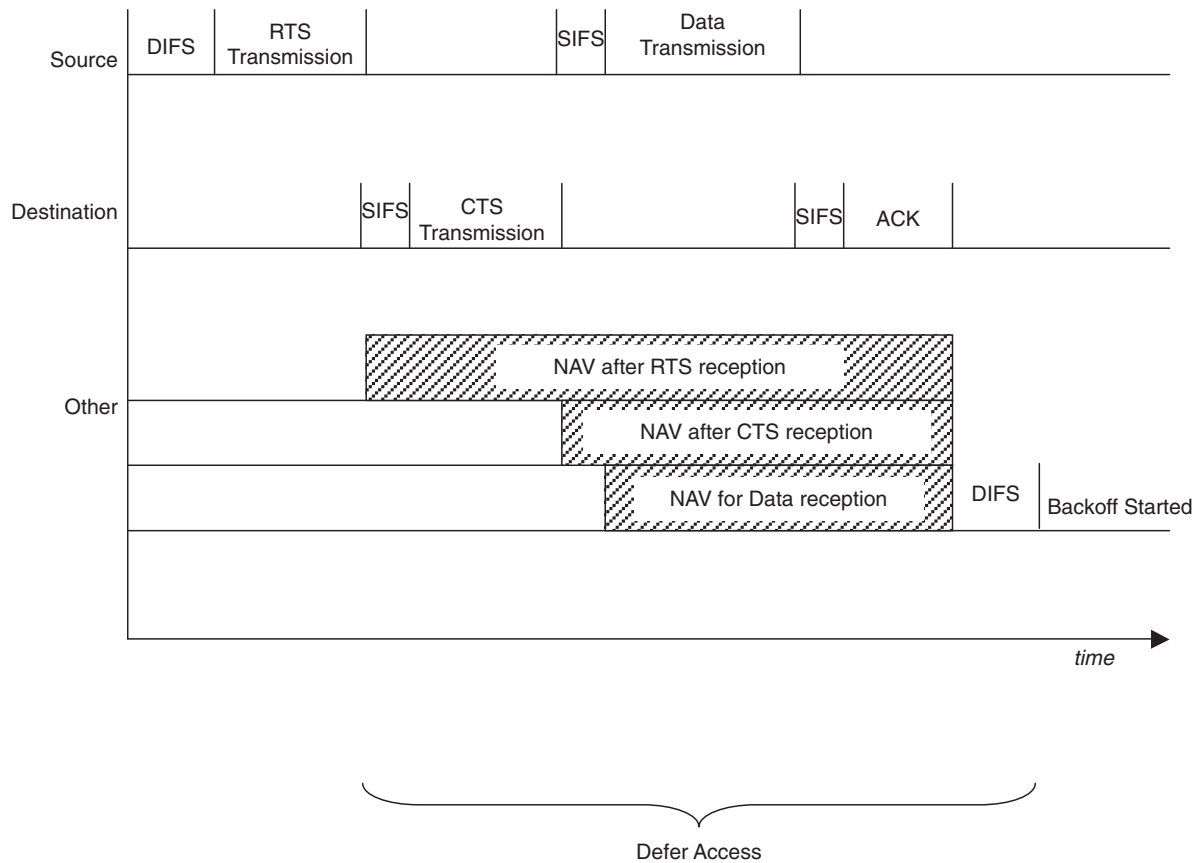

Figure 8: Frame transmission along with the changes in the NAV as time progresses

the SIFS durations that separate each one of these. When the receiver gets the RTS, it waits the length of a SIFS duration and sends back a CTS. Upon receiving the CTS, the sender waits the length of another SIFS and transmits the data packet, which is followed by another SIFS and an ACK. The success of these steps marks a successful packet transmission. Nodes wait the length of a DIFS duration and contend for the channel again.

Following a busy channel, the probability of more than one node trying to access the channel is high. The idle period following a DIFS interval is referred to as the contention window. To prevent collisions and enhance the performance, nodes enter into a back-off period so that channel access demands are spread across time. Nodes calculate a random back-off interval. A station calculates the amount of backoff to be between 0 and the minimum size of the contention window (CW_{min}). A station transmits only when its backoff reaches 0 and the channel is idle. In case the transmission results in a collision, the station calculates a new contention window size equal to $2^{2+i}-1$ time slots, in which i equals the number of consecutive collisions the station experienced. For every transmission failure, the station calculates a contention window until it reaches a maximum window size (CW_{max}). When the retry counter, i , exceeds a specific (user-defined) value, the packet is dropped. The countdown timer freezes when the channel is sensed to be busy, and it is resumed once the wireless medium is detected to be idle, subsequently for DIFS time.

Access Modes: PCF

Unlike DCF, which is a contention-based protocol used for data traffic, the point coordination function (PCF) provides a contention-free protocol that can be used for connection-oriented real-time traffic (e.g., voice). This is done by polling the stations one at a time. PCF needs an element called a point coordinator (PC), which decides when (and which) nodes can transmit according to a polling list (normally in round-robin fashion). The PC is recommended to be integrated with the AP. Given the centralized approach of PCF, which depends on the AP for polling, PCF works only for the infrastructure-based topologies and not for the ad hoc one. In addition, PCF has not yet been implemented and is not available in any WLAN card. The protocol works by dividing time into contention-free periods (CFPs). The length of the CFP is manageable and determines how often the PCF runs. Each CFP consists of a contention-free portion followed by contention-based period (i.e., for DCF traffic). Each CFP must allow for at least one DCF packet to be transmitted (so that DCF traffic does not starve). The portion allotted to PCF traffic is dynamic, and the AP can change it as the traffic requirements change. For example, if a small number of nodes is interested in the PCF service, more time is allotted to the DCF function. The AP announces the beginning of a CFP by sending a beacon frame. Stations update their NAV to the maximum length of CFP, which is a defined parameter, *CFP_Max_Duration*. Periodically, the AP sends a

beacon frame that contains the remaining time of the CFP, *CFPDurationRemaining*.

To initiate the beginning of a CFP, the AP waits a PCF inter-frame space (PIFS), which is shorter than a DIFS. Thus, the AP gains access to the channel before any DCF station does. It then sends a beacon frame, which is used for synchronization and parameter information announcement. At this point, all stations have updated their NAV, and no one will access the channel unless requested by the AP. The AP can send a poll frame, a data frame (i.e., forwarding from one station to another), a combination of data and poll, or a CFP end frame.

802.11 PHYSICAL LAYER

This section explains basic concepts related to the physical layer, followed by a discussion of the main problems associated with wireless channels. Afterwards, the different radio layers of the 802.11 standard are described. The section closes with a brief look at some of the physical layer standards.

Concepts

Channel Coding and Modulation

Modulation is the process of changing the data stream to a form suitable for transmission over a physical medium. Two categories of modulation exist: analog modulation and digital modulation. Analog modulation works by impressing the analog signal containing the data on a carrier wave, with this impression aiming to change a property of the carrier wave. Digital modulation refers to the mapping of one or more bits to a symbol; the symbol is the basic unit communicated between transmitter and

receiver. This works by converting a bit string (digital data) to a suitable continuous time waveform. This conversion involves modifying one of the signal characteristics (amplitude, frequency, or phase), giving rise to amplitude modulation, frequency modulation, or phase modulation (see Figure 9). Amplitude refers to the signal strength; frequency refers to the number of times per second the signal repeats its pattern (measured in Hz or cycles/sec); and phase is the relative position in time.

In digital modulation, the higher the number of bits mapped to a symbol, the denser the modulation scheme. The denser the modulation scheme, the more spectrally efficient it is. The number of bits per symbol depends on the modulation scheme used. For example, if the channel bandwidth is 1 MHz, the wave frequency is fixed and equal to the frequency of the carrier wave; if every bit is mapped into a symbol, the channel capacity is 1 Mbps. This holds because 1 million wave transitions per second are supported. On the other hand, if every two bits are mapped into one symbol, the channel capacity will be double to 2 Mbps. Nonetheless, the increase in the number of bits per symbol is not arbitrary. The higher the number of bits per symbol, the higher the chances of error in recovering the bits at the receiving end.

Coding allows for maximizing the benefit of transmission over noisy wireless channels by introducing redundancies in the bits transmitted, so that the receiver can still recover a reasonably distorted packet. To be able to recover more errors, more overhead bits have to be sent. Coding efficiency refers to the ratio between data to total bits in the stream. For example, a coding efficiency of $\frac{1}{2}$ means that, for every bit in the data stream, two bits have to be sent. One important issue with regard to coding schemes is the computational complexity of implementing

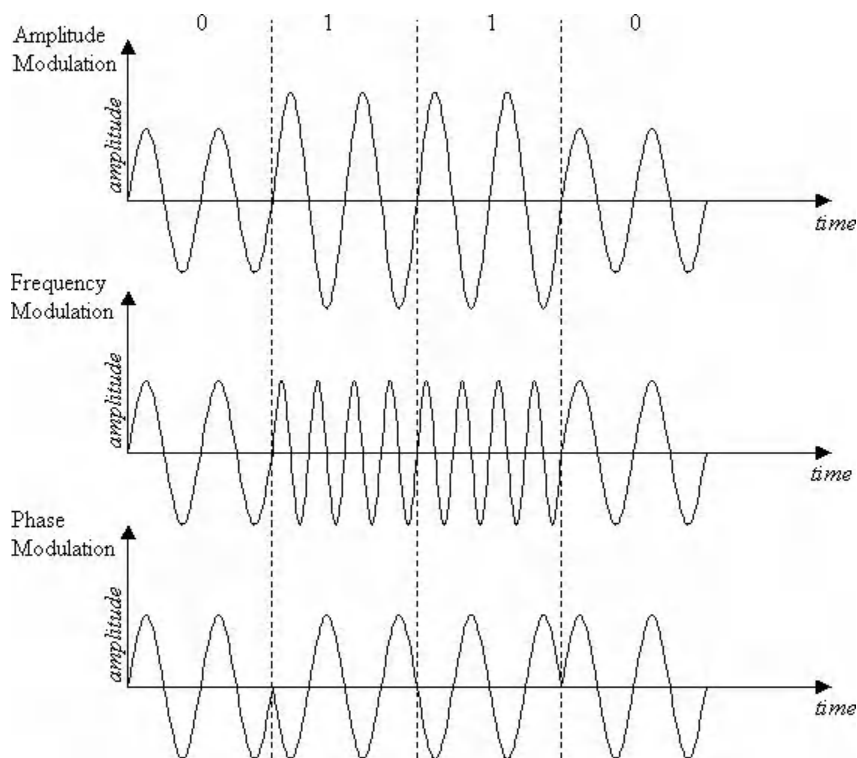

Figure 9: Illustration of amplitude, frequency, and phase modulations (bit sequence: 0110)

the code. This is especially important for portable wireless devices, which try to use their energy efficiently.

Antennas

An antenna is a device responsible for emitting or collecting electromagnetic waves for the purposes of transmission and reception. In other words, it is the interface between the transmitter/receiver and the air. An antenna takes electrical signals from the transmitter and converts them into radio (i.e., electromagnetic) signals sent on the air, and captures radio signals from the air and converts them into electrical signals at the receiver. Antennas are characterized by many parameters, including directivity/gain, polarity, and efficiency, among others (Antenova, Ltd. n.d.).

Before explaining directivity, isotropic antennas need to be defined. An isotropic antenna is an idealistic antenna, which radiates the same power in all directions. In other words, if we create a sphere around it and measure the power intensity at any point on the surface, the same value is achieved. Realistic antennas radiate more in some directions than others. Gain is the amount of power *gained* in one direction at the expense of other directions.

Electromagnetic waves consist of coupled electric and magnetic fields. Polarization refers to the position and direction of the electric field with reference to the earth's surface. An antenna can be horizontally or vertically polarized. The transmitting and receiving antennas have to have the same polarization; otherwise, a great amount of loss will occur. Efficiency of an antenna is defined as the ratio between the radiated power and the input power. An isotropic antenna has a gain of one.

Antennas can be omnidirectional, providing a 360-degree radiation pattern; directional, in which they focus their radiation in one direction to provide greater coverage distance; and diversity antennas, which actually use more than one antenna for signal reception and, when transmitting, send through the antenna with the best received signal.

Wireless Problems

Unlike wired transmissions, the wireless channel is characterized by much impairment, which—along with the scarce spectral bandwidth—makes achieving wired medium quality extremely difficult. In this subsection, the problems faced by wireless communications are briefly noted.

Path loss. As a signal propagates from the transmitter to the receiver, it attenuates (i.e., loses its energy) with distance. Thus, the longer the distance, the weaker the signal received. The free space model refers to the signal strength when the path between the transmitter and the receiver is clear of obstacles and resembles a line of sight. In the free space model, the signal attenuates with the square of the distance (i.e., d^2 , where d is the distance; Nicopolitidis et al. 2003). Realistic modeling of path loss, however, depends on many other factors, including the reflecting objects and big obstructions in the path between the transmitter and the receiver. Depending on the model at hand, the signal strength decreases with distance with an exponent ranging from 3 to 6.

Figure 10: Illustration of a multipath propagation (numbers on the rays refer to path numbers)

Multipath fading and shadowing. When a signal is transmitted, multiple versions of the same signal take different paths in arriving to the receiver (see Figure 10). The first to arrive at the receiver is the one going through the line of sight (LOS), which is the path that does not have any obstacles between the transmitter and the receiver (Path 2 in Figure 10). Other, delayed versions follow other paths resulting from impingements on obstacles in the path. When these delayed copies arrive at the receiver, they either add constructively or destructively. Notice that the obstacles in the path are not fixed in number or position. Mobility of the transmitter, receiver, or the objects in between, changes the paths between the transmitter and the receiver. Thus, the signal quality varies with time. This phenomenon, in which the signal quality depends on the multipath propagation, is referred to as multipath fading. Another type of fading is shadow fading. When the signal encounters a large obstacle in its way, such as a building, it is attenuated severely. The amount of absorption depends on the characteristics and size of the obstacle.

Interference. Interference refers to extraneous, unwanted signals that affect the proper system operation. Not only does interference affect the quality of the signal communicated from the transmitter to the receiver, but it can also affect the functionality of the protocol. For example, the existence of another 802.11 network in the vicinity could make sources sense the channel as busy even though it is not.

Since wireless LANs work in the ISM band, which does not require any licensing, they are especially susceptible to interference. Microwave ovens, photocopying machines, medical equipments, Bluetooth-enabled devices (e.g., PDAs or laptops), and wireless phones are examples of possible sources of interference. Obviously, the existence of another WLAN segment cannot be ruled out, especially as WLANs gain more acceptance in the marketplace.

Many things can be done to deal with interference. Conducting site surveys to understand the geographic area in which the WLAN will work, maintaining strong coverage by transmitting high-power signals, and shutting down other devices that can interfere are examples of procedures that can help. As will be discussed later, wireless LANs circumvent this problem by using spread spectrum techniques (Geier 2002b).

The Radio Link

The IEEE 802.11 WLANs use either radio or infrared electromagnetic waves for data transmission. This

Figure 11: A four-channel FHSS system

section and the next will discuss both of these interfaces. Radio-based WLANs, which are more common than IR-based WLANs, operate at the ISM band because this band does not require any licensing from the FCC. The standard defines two physical layer methods: frequency hopping spread spectrum (FHSS) and direct sequence spread spectrum (DSSS). The basic idea of spread spectrum (whether FHSS or DSSS) involves using a very wide bandwidth to communicate data. By increasing the bandwidth used, communication will be more resilient to interference and fading because only a small portion of the bandwidth will be affected.

Frequency Hopping Spread Spectrum Physical Layer

In FHSS, the signal is spread by sending one frequency for a short period of time and then switching (hopping) to another frequency in a seemingly random fashion (see Figure 11). The hopping sequence and rate are predefined and known to both the sender and the receiver. Two types of FHSS systems exist, depending on the hopping rate. If multiple bits are transmitted over the same frequency channel, the system is called slow frequency hopping. On the other hand, if the hopping rate is greater than or equal to the bit rate—that is, if one bit or less is transmitted over a channel—the system is considered fast frequency hopping. Because wireless LANs operate on the ISM band, many sources of interference may exist. If a source of interference happens to be in the vicinity of a slow frequency hopping transmission and is operating at a frequency that is also used by the slow FH system, it will corrupt all packets sent at that frequency channel. In a fast frequency hopping system, on the other hand, very few noise spikes will take place, and the receiver will still be able to recover the data. Thus, fast hopping systems have better interference resilience (Bing 2000).

The time spent in every frequency, known as the dwell time, is limited by the FCC to a maximum of 400ms. This means that the FHSS system hops at least 2.5 times per second. In addition, the number of frequency channels used in the hopping sequence cannot go below six channels (i.e., 6MHz; Roshan and Leary 2004). The 802.11 standard splits the available bandwidth into seventy-nine channels, each 1 MHz wide.

The 802.11 physical layer supports two data rates: 1 Mbps and 2 Mbps. It consists of two sublayers: the physical layer convergence protocol (PLCP) and the physical medium dependent (PMD). PLCP is responsible for adding necessary headers for the purposes of synchronization, timing, and error control. The PMD is responsible for the raw transmission of bits over the air; it mainly performs modulation of the data stream.

The PLCP adds a 128-bit header to frames arriving from the MAC layer (called PLCP service data units, or PSDU). The header contains the following fields:

- A preamble, which has two subfields (96 bits):
 - Synch: An 80-bit sequence of alternating 0s and 1s starting with a 0. It is used at the receiver for time synchronization. In addition, if the receiver is using any antenna diversity technique, it uses these bits to choose the best antenna. The transmitter and the receiver must be synchronized so that they switch from one frequency to another at the same time.
 - SFD (start of frame delimiter): A specific bit string (0000 1100 1011 1101) used at the receiver for frame timing.
- PSDU length word (PLW): A 12-bit field that indicates the size of the MAC frame.
- PLCP signaling field (PSF): A 4-bit field used to specify the data rate at which the frame was transmitted. Data rates range from 1 Mbps to 4.5 Mbps in increments of 0.5 Mbps. Table 1 shows the possible values along with the data rates they indicate (Nicolopolitidis et al. 2003).
- Header error control (HEC): An ITU-T cyclic redundancy check, CRC16 used for error detection.

After receiving a bit stream from the PLCP sublayer, the PMD modulates it using Gaussian frequency shift keying (GFSK). Depending on the data rate supported (whether 1 Mbps or 2 Mbps), GFSK or 4GFSK is used. 4GFSK translates every two bits into one signal element, doubling the rate. Frequency shift keying schemes, in general, convey the information by changing the frequency of the signal. Thus, the amplitude of the signal does not carry any information. This provides the flexibility of changing the

Table 1: PSF Field Value with the Data Rate Supported

Field Value	Data Rate (Mbps)
000	1
001	1.5
010	2
011	2.5
100	3
101	3.5
110	4
111	4.5

transmission power as needed. In addition, the design of the transmitter and the receiver is simple. An important drawback of FSK-based schemes is that they are not spectrally efficient. That is, the amount of information conveyed per signal element is small when compared with other modulation schemes. Figure 12 shows a block diagram of an FHSS transmitter. The input bits are fed into a GFSK modulator, which produces an analog signal from the data. A spreader that takes a pseudo-random number as an index for table look-up uses the table entry's frequency as the carrier frequency to be modulated by the output of the GFSK modulator. The resultant signal is the one transmitted in the air. The opposite process takes place at the receiving end to demodulate the received signal (Roshan and Leary 2004).

Direct Sequence Spread Spectrum Physical Layer

The main idea of DSSS is to spread the signal energy across a large bandwidth. To other unintended receivers, the signal can be treated as noise that can be easily rejected. As a result, the same frequency band can be used by multiple DSSS signals, allowing for better bandwidth usage while minimizing interference effects.

To achieve this spreading, DSSS systems map every bit in the data stream to an m-bit pattern called the pseudo-noise code, or chipping code. The number of bits in the code determines the spreading factor. The higher the spreading factor, the more resilient the signal to interference. However, this is at the expense of bandwidth requirement, which shoots up. The FCC specifies a minimum spreading factor of 10. That is, a maximum data rate of

10 percent of the available channel bandwidth can be provided. The IEEE 802.11 uses an 11-chip spreading factor; every bit in the data stream is replaced by 11 bits (chip sequence) to be transmitted over the channel. Even though this may seem very expensive, the fact that it minimizes interference effects results in enhancing channel quality, which translates into fewer corrupted packets, better overall throughput performance, and decreased transmission delay as the need for retransmissions is reduced.

The receiver of a DSSS signal has to know the chipping code mappings and has to be synchronized to the correct phase of the code. That is why every packet is prefixed with a preamble for synchronization purposes.

An important difference between code division multiple access (CDMA) systems and the DSSS system used by the 802.11 is that CDMA is based on code multiplexing. That is, multiple transmissions can take place at the same time as long as different communication pairs are tuned to different codes. This requires the availability of a code pool to choose from, the logic to choose a code, and complex receivers synchronized for a specific code. In contrast, DSSS wireless LANs use the one code allowing for broadcast communication (Bing 2000).

The 802.11 DSSS physical layer supports two rates: 1 Mbps and 2 Mbps. A subsequent standard—the 802.11b—supports data rates of 5.5 Mbps and 11 Mbps. Like the FHSS physical layer, the DSSS physical layer consists of two sublayers: the PLCP and the PMD. The PLCP of DSSS is very similar to that of FHSS and serves the same purpose. The PMD modulates the data stream for transmission over the channel. The channel bandwidth supported by the 802.11 standard is 11 MHz; given that the spreading factor is 11, the data rate that can be supported is either 1 Mbps or 2 Mbps. The rate depends on the modulation scheme used. The DSSS physical layer uses differential binary phase shift keying (DBPSK), in which every symbol carries one bit, allowing for a data rate of 1 Mbps. To support the 2 Mbps rate, differential quadrature phase shift keying (DQPSK) is used, in which every symbol carries two bits from the data stream. Thus, in both cases, 1 mega symbols are being communicated. The difference lies in how many bits a symbol maps to.

Infrared

This chapter has already discussed the radio-based flavor of wireless LANs. Unlike radio-based WLANs, infrared is not regulated; hence, plenty of bandwidth is available. In addition, infrared does not suffer from the electromagnetic

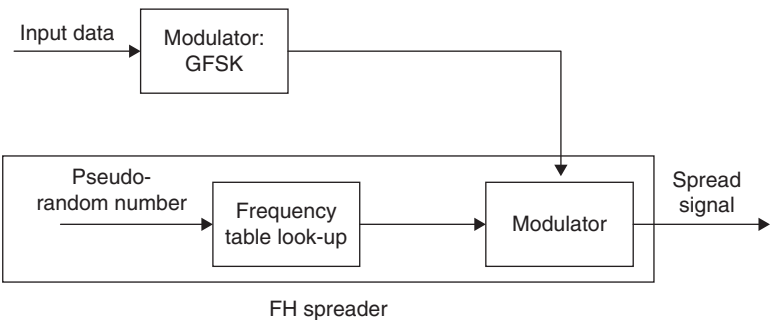

Figure 12: FHSS transmitter

interference that is a limiting factor for radio-based WLANs. However, infrared has its own sources of interference (e.g., sunlight, fluorescent light, etc.), which can substantially degrade network performance. Like visible light, infrared does not penetrate opaque objects (e.g., walls), which entails the need for an access point in every room. Even though this may seem to be a disadvantage, especially because an AP can provide large coverage in radio LANs, it actually has great advantages. First, it promises secure communication, because eavesdropping (or any security attack for that matter; e.g., denial of service) is very difficult from the outside. Second it provides interference immunity, allowing each room a separate deployment; thus, large IR LANs can be built (Stallings 2002). Finally, infrared wireless LANs are simpler to implement and hence are less expensive. This is attributed to their use of intensity modulation for data transmission, which only involves detecting the signal's amplitude—unlike radio systems, in which the frequency and/or phase needs to be detected.

One main issue of infrared LANs is the absence of products in conformance with the standard. This limits deployment of infrared LANs to small-scale usage under one management domain. Two main types of IR LANs exist: directed and omnidirectional. A directed IR LAN is used to create point-to-point connections. The transmitter and the receiver have to be placed so that a line of sight exists between them. Depending on the transmission power used, directed transmissions produce high performance in terms of transmission distance, bandwidth, and throughput achieved. Data rates ranging from 1 to 155 Mbps over a distance of 1 to 5 km can be provided (Bing 2000).

Directed IR can be used in a campus-sized network in which different segments need to be connected to one another. To do so, directed links across buildings are created to connect bridges or routers. Indoors, directed IR can also be used to connect different segments in any suitable arrangement (e.g., to connect Ethernet or token ring segments; Stallings 2002). Omnidirectional IR can be used for scenarios similar to radio LANs. A ceiling-mounted transceiver broadcasts to all nodes within a line of sight (e.g., in a room). Omnidirectional IR can be used only in an indoor environment because it relies on reflections off of objects (e.g., walls, ceilings, desks, etc.) to propagate in all directions. Even though these reflected copies allow for the freedom of aligning the transmitter and receiver, a substantial amount of the energy is lost, limiting the data rate and range of communication. Indoor omnidirectional IR LANs operate at a rate limited to 4 Mbps within a range of 10 to 20 m (Bing 2000).

Physical Layer Standards

New standards have been approved that achieve higher data rates. This section briefly discusses the main differences between the 802.11 standards a, b, and g, and how these higher rates are achieved.

IEEE 802.11b

The 802.11b defines the high rate DSSS (HR-DSSS), which allows data rates as high as 5.5 Mbps and 11 Mbps (IEEE 802.11b Working Group 1999). The PLCP of the

HR-DSSS defines two types of frames: long and short. The long frame format is basically the same as in DSSS. A few fields have been added, mainly to define the data rate communicated (whether 5.5 Mbps or 11 Mbps) and the modulation scheme used. The preamble and header are always communicated at a rate of 1 Mbps to ensure backward compatibility with DSSS. The short frame has the same format as the long one, except that fewer bits are used for a field to minimize overhead. For example, as opposed to 128 bits for synchronization in the long frame, only 56 are used in the short one. The other difference is that the short frame's preamble and header are communicated at a rate of 2 Mbps (as opposed to 1 Mbps in the long frame). As before, the PMD is basically responsible for modulating the bit stream that it receives from the PLCP (Roshan and Leary 2004).

Two modulation schemes are used: complimentary code keying (CCK) and packet binary convolutional coding (PBCC). Higher data rates are achieved in the following manner. As before, an 11 MHz bandwidth is used. However, the spreading code is 8 chips long rather than 11 chips in the 1 Mbps and 2 Mbps cases. In addition, the number of bits in an 8-chip code is different. Using the CCK modulation, every 4 bits from the data stream are encoded in an 8-chip code, thus allowing for a data rate equal to

$$11 \times 10^6 \times \frac{4 \text{ bits}}{8 \text{ chips}} = 5.5 \text{ Mbps} \quad (1)$$

Similarly, the PBCC modulation scheme codes 8 bits in an 8-chip code, allowing for a data rate of 11 Mbps.

IEEE 802.11a

Unlike the 802.11b, which works in the 2.4 GHz ISM band, the 802.11a works in the Unlicensed National Information Infrastructure (UNII) 5 GHz band (IEEE 802.11a Working Group 1999). It supports data rates up to 24 Mbps and optionally up to 54 Mbps. Three hundred MHz are used in 802.11a, which are then divided into three 100 MHz bands—each with different maximum power output. The three bands used are 5.15–5.25 GHz, 5.25–5.35 GHz, and 5.725–5.825 GHz. Devices operating at these bands produce a power equal to 50 mW, 250 mW, and 1 W, respectively. The high power output allowed in the high band makes it more suitable for building-to-building devices (e.g., bridges connecting two LAN segments). The other two bands are suitable for indoor environments. Data is modulated using the orthogonal frequency division multiplexing (OFDM) scheme. The basic premise of OFDM is to minimize the inter-symbol interference (ISI) problem, which occurs when a symbol takes longer to reach the receiver. This delay, called delay spread, results from multipath propagation (discussed earlier). Because of this delay, a symbol may arrive at the same time as another subsequent symbol. This can be dealt with by decreasing the number of symbols per second, thus ensuring that a symbol has an ample amount of time to reach the receiver before a subsequent symbol is sent. Obviously, this decreases the data rate achieved. Hence, OFDM breaks the channel bandwidth into subchannels.

Table 2: Supported Data Rates and the Modulation Schemes Used

Data Rate (Mbps)	Modulation Scheme
6	BPSK
9	BPSK
12	QPSK
18	QPSK
24	16-QAM
36	16-QAM
48	64-QAM
54	64-QAM

Each subchannel has a low symbol rate and thus a low ISI. The subchannels are chosen to be orthogonal; as a result, low co-channel interference occurs. A receiver tuned at a given frequency sees all other signals as zero. Table 2 shows the data rates supported by the 802.11a standard along with the modulation scheme used.

IEEE 802.11g

The 802.11g standard is very recent. It was approved in 2003 and supports data rates up to 54 Mbps (IEEE 802.11g Working Group 2003). Unlike the 802.11a, the 802.11g operates in the ISM 2.4 GHz and has backward compatibility with the 802.11b. If all the devices in the network talk 802.11g, the high data rates of 802.11g can be used. However, if any of the devices in the network talks 802.11b, all other devices have to switch to the low data rates supported by the 802.11b. The mandatory data rates are 6, 12, and 24 Mbps; the rest are optional. To ensure backward compatibility, the packet header and preamble are sent using CCK modulation, which is also used by the 802.11b, and the payload is sent using OFDM.

HIPERLANs

HIPERLAN Type 1

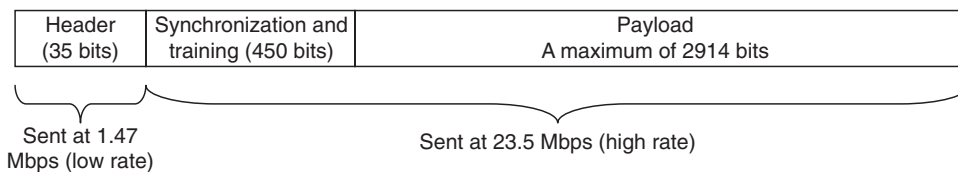

The high performance radio LAN (HIPERLAN) type 1, developed by the European Telecommunications Standards Institute, is the European counterpart of the IEEE 802.11. The protocol provides data rates up to 23.5 Mbps and supports low mobility conditions (1.4 m/s). Like its counterpart, its reference model (shown in Figure 13) covers both the physical (PHY) and the MAC layers. The physical layer is responsible for transmission/reception of raw data over the wireless channel. The channel access control (CAC) sublayer determines how nodes will access the

**Figure 13:** HIPERLAN/1 reference model

channel and which nodes have the right to access by allowing access priority to be specified. The MAC defines the different protocols responsible for power conservation, multihop forwarding, security, and data transfer to upper layers (Broadband Radio Access Network [BRAN] 1998; Jain 2007; Papadimitriou et al. 2003).

Unlike the 802.11, HIPERLAN/1 has a single physical layer that is not based on spread-spectrum techniques. It uses a narrowband modulation in the 5.15–5.30 GHz range. It is important to note that HIPERLAN does not provide an infrared physical interface. Two data rates are supported: a lower rate of 1.47 Mbps, which uses FSK modulation, and a high rate of 23.5 Mbps, which employs GMSK as a modulation scheme. Thus, every packet contains a low-rate header (sent at 1.47 Mbps) followed by a high rate header plus payload (sent at 23.5 Mbps; see Figure 14). By merely looking at the low-rate header, a node can decide whether it needs to listen to the rest of the packet. This way, an over-hearing node can save power by turning off its error correction, equalization, and other functionalities as soon as it realizes it is not the intended destination of a packet. Note that Figure 14 will be clearer after the next paragraph (Bing 2000).

As the data rate transmitted over a wireless channel increases, the effect of intersymbol interference (ISI) increases. Symbol duration becomes smaller, and, as a result, delay spread effect grows. To circumvent this problem, decision feedback equalization is employed. An equalizer eliminates the effect of ISI without enhancing the noise. Equalization involves a training sequence, which is known to the receiver to be transmitted by the sender. Upon receiving this sequence, the receiver compares it with the already known sequence and adjusts its filter coefficients. At this moment, the receiver is ready to receive user data. Periodically, the receiver will need retraining to ensure effective ISI cancellation. The HIPERLAN standard does not specify what equalization technique should be used, leaving this decision to protocol implementers. GMSK has excellent power efficiency and spectral efficiency. It is a constant envelope scheme, which means that the amplitude of the signal is constant. Hence, highly efficient power amplifiers can be used (no information

**Figure 14:** HIPERLAN/1 packet format (Bing 2000)

loss will occur from nonlinear amplification because the signal amplitude is not carrying any information; Rappaport 1996). In addition, forward error correction (FEC) is used to increase the throughput by minimizing the need for retransmissions of bad packets. The broadcast channel (BCH) is used where every 26 bits are coded to 31 bits (Nicolaitidis et al. 2003).

The MAC protocol of HIPERLAN/1 supports both asynchronous (data) and isochronous (audio and video) applications. The protocol does not reserve bandwidth for different users or application classes. However, it provides QoS by means of the supported priority-scheduling scheme, favoring higher-priority packets and taking into account their lifetime. The HIPERLAN/1 MAC protocol is distributed, allowing for both infrastructure and ad hoc, multi-hop topologies. A node that senses the channel idle for 1700 bit times (in the high data rate) can transmit its packet with no overhead involved. However, the chances of the channel being idle for 1700 bit times are extremely low, even for moderate load conditions. Thus, another mechanism can also grant channel access, which involves the use of the elimination yield–non-preemptive multiple access (EY-NPMA). A station that senses a busy channel first waits until the channel becomes idle, then waits for 256 bit times (called the synchronization slot), and finally runs the EY-NPMA. In an EY-NPMA scheme, channel access involves going through three phases (listed as follows), each of which can be thought of as a screening phase. In every phase, some nodes will drop from the competition, and the rest will continue on to contend in the next phase. The third phase, however, does not guarantee a single winner; thus, collisions—although unlikely—are still possible.

1. The prioritization phase consists of five slots, allowing for five priority levels. A station with priority r transmits a burst in slot $r+1$, indicating a busy channel if and only if it does not sense a higher-priority burst. The higher the node's priority, the faster it can get hold of the channel. At the end of this phase, one or more nodes (all with the same priority) will move on to the next phase. All others will have to wait until the next synchronization slot.
2. The elimination phase is thirteen slots long. In this phase, stations that survived the previous phase transmit a burst for a number of slots geometrically distributed with a parameter $P = 0.5$. Thus, the burst length is 1 slot with probability $\frac{1}{2}$, 2 slots with probability 0.25, and so on. Each station, at the end of its burst, senses the channel to see if a longer burst has been transmitted

by other stations. If yes, the station stops contending for the channel. If no, the station continues to the next phase. Obviously, the chances of having more than one winner in this phase grow with the increase in the number of nodes that make it from the previous phase.

3. The yield phase is fifteen slots long. All of the stations that made it to this phase back off for s slots, where s is geometrically distributed with a parameter $P = 0.1$. A station that senses an idle channel at the end of its back-off interval can transmit its packet.

An overview of the EY-NPMA protocol is shown in Figure 15.

HIPERLAN/1 supports ad hoc topologies using a process called interforwarding. In simple terms, nodes can communicate with nodes out of their reach by transmitting to their neighbors, who forward the communication to their neighbors, and so on until the communication reaches its intended destination. For this to work properly, nonforwarding nodes need to know their direct neighbors, and forwarding nodes need to know routing information (i.e., the next hop to get to a particular destination and the path length). The forwarding function is optional, and a node may choose not to forward traffic. A node can forward packets in two modes: point-to-point and broadcast. In broadcast mode, the forwarding node, called a multipoint relay, forwards the packet to all neighbors. Nonmultipoint relays do not forward packets they receive. The set of multipoint relays is chosen as the minimum set that covers all nodes within two hops from the node, thus minimizing the number of forwarding nodes.

Like other ad hoc networks, the multihop mode of HIPERLAN has many problems. The dynamic nature of a network in which nodes come and go makes maintaining correct information about the topology very difficult. In addition, the overhead involved in maintaining this information is very costly, especially in terms of energy because mobile nodes are battery operated. Another problem that is aggravated in a multihop network is the wireless channel conditions. Dual Doppler effect (both sender and receiver are mobile), interference caused by parallel transmissions, and fading all make the chances of a packet successfully reaching its destination very small.

HIPERLAN Type 2

Upon completion of the HIPERLAN/1 standard, the ETSI decided to merge wireless LANs and wireless local loop, the communication between the end user and the service

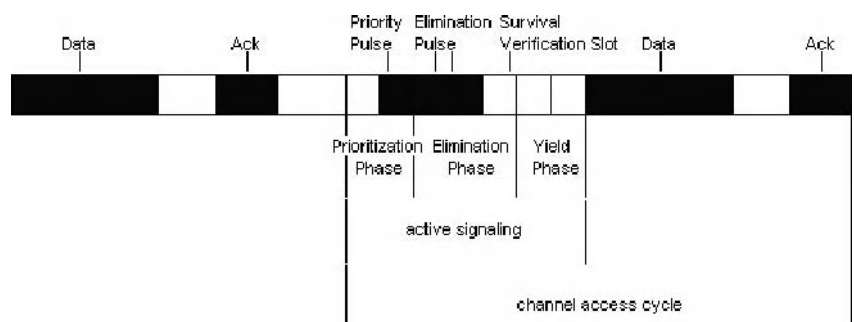

Figure 15: The EY-NPMA protocol

provider, into one protocol called the broadband radio access network (BRAN). The BRAN project standardizes wireless ATM protocols, includes HIPERLAN types 2, 3, and 4.

HIPERLAN/2 is very different from HIPERLAN/1 and has many salient features as follows (BRAN 2001; Johnsson 1999; Nicopolitidis et al. 2003):

- High data rates: HIPERLAN/2 supports data rates up to 54 Mbps.
- Connection-oriented: Communication between stations and the AP is connection oriented. A connection is established prior to any data transmission.
- QoS support: Connection orientation and the provision of high data rates enable HIPERLAN/2 to provide QoS support.
- Automatic frequency allocation: Unlike cellular networks in which static radio frequency planning is performed, the AP in HIPERLAN/2 performs dynamic frequency channel selection that is not in use by other APs, which minimizes co-channel interference.
- Power saving: A mobile station can communicate to the AP its desire to schedule sleep periods in order to minimize power consumption. At the end of every sleep period, the station wakes up to see if the AP has sent any wake-up indication. If not, the station can go back to sleep for another period.

The physical layer of HIPERLAN/2 is very similar to the physical layer of the 802.11a. They both operate in the 5 GHz band and use OFDM. In addition, both offer data rates as high as 54 Mbps. To a certain extent, the same modulation and coding schemes are used. However, their synchronization and training sequences differ.

Differences between the two protocols appear in the MAC layer. The 802.11 is based on the CSMA/CA protocol. One problem with CSMA/CA is that it is probabilistic: a station does not have any guarantee that within a given time period it will be granted the channel to transmit. These delays render the support of any real-time application very difficult, even under moderate load conditions. HIPERLAN/2 is based on dynamic time division multiple access (TDMA) with time division duplexing (TDD). In a TDMA scheme, stations are dynamically assigned time slots according to their needs. Time slots are dynamically allocated depending on transmission needs. TDD means that part of the frame is used for the uplink (communication between the stations and the AP), and part for the downlink (from the AP to the stations). Once assigned a time slot, a station can transmit on a regular basis during its slot. The AP notifies the stations when it is their time to transmit (Doufexi et al. 2002; Papadimitriou, Lagkas, and Pomportsis 2003).

A MAC frame has a duration of 2 ms and consists of different channels, as shown in Figure 16. The broadcast channel is a downlink channel through which the AP

sends control information to all nodes in the network. This includes transmission power level, wake-up indicator, and identifier of the AP and the network, among other things. The frame control channel (FCH) is also a downlink channel that is used to announce how the rest of the current MAC frame has been allocated (i.e., how much for the uplink, for the downlink, and for contention). The access feedback channel (ACH), also a downlink channel, conveys information regarding previous random access attempts that took place in the RCH. The downlink and uplink phases consist of a number of packets to be communicated from and to the AP, respectively. The number of slots and how many per station is based on the AP announcements during the FCH channel. The random access channel (RCH) is an uplink channel used to compete for slots in subsequent MAC frames. Results of contention are reported back to stations in subsequent frames' ACH channels (Johnsson 1999).

WLANs SECURITY

Wireless networks are more vulnerable to security threats than wired networks because of the broadcast nature of the wireless channel. Any node within the transmission range of a wireless LAN can access it, thus enforcing security measures is of high importance in a wireless LAN. Two mechanisms are generally used to minimize security threats: authentication and encryption. Authentication ensures that only authorized nodes can access the network, and encryption ensures that confidentiality is maintained (Obaidat and Boudriga 2007).

Encryption in 802.11

Encryption is the process of transforming human-readable data (the plain text) into an unreadable form (the cipher text). Encryption and decryption typically involve the use of a common secret between the sender and the receiver (the encryption key). Figure 17 illustrates the idea of encryption. Two types of encryption exist: block cipher and stream cipher. They both involve generating a key (the stream key) from a basic secret key. In block cipher, the plain text is divided into blocks, and each block is encrypted using a fixed-size stream key. In a stream cipher, on the other hand, the data stream is processed continuously (e.g., taking one byte at a time). In addition, the stream key size is not fixed. Block ciphers provide higher levels of security than stream ciphers, but they are more computationally demanding.

The 802.11 standard uses the wired equivalent privacy (WEP) protocol, which is based on the RC4 encryption algorithm. RC4 is a stream cipher that uses symmetrical keys; if the sender uses a key K_1 to encrypt the data, the receiver uses the same key (i.e., K_1) to decrypt it. Symmetrical key encryption is simple and requires very trivial amounts of computation. The protocol tries to minimize the computation penalty introduced by encryption using

Figure 16: Format of the MAC frame in HIPERLAN/2

Figure 17: Block diagram of the encryption process

stream, symmetric algorithm. The protocol does not provide any key distribution mechanism and thus assumes the keys to be manually configured in the client stations as well as the access point. Two key lengths are supported: 40 bits and 104 bits. The longer the key, the more difficult it is for an attacker to conduct a brute force attack in which all possible keys are tried.

If every time an encryption algorithm is fed a plain text P and generates the same cipher text C , then that algorithm is described as an electronic code book (ECB). An attacker can do cryptanalysis to find patterns in the cipher text that can help him break the encryption. To provide higher security, WEP circumvents this problem using a concept called initialization vectors (IVs). The goal is to change the encryption algorithm's output even if fed the same plain text. Thus, the encryption of a string P results in a cipher text C_1 ; if the algorithm is run again, using the same string P , it will produce a cipher text C_2 , and so on.

An IV is nothing but a number to be added to the key, which results in a new key. To ensure high randomness in the cipher text, the IV should be changed for every frame sent. For the receiver to be able to decrypt the message, it needs access to the IV value used at the sender, which is why every frame sent carries with it the IV used. The encryption process involves the following steps (Roshan and Leary 2004):

1. For every arriving frame, generate a 24-bit IV and append it to the secret key K_1 , resulting in a stream key K_2 .
2. Calculate the integrity check value (ICV) of the arriving frame. The ICV is a CRC-32 that is used to ensure that the frame has not been tampered with or corrupted in transmission.
3. Encrypt both the frame payload and the ICV using K_2 .
4. Create a frame that contains the encrypted payload, the encrypted ICV, and the IV used for the encryption.

The opposite process takes place at the receiving end. The receiver extracts the IV value, constructs the stream key, uses it to decrypt the payload and the ICV, and finally compares the decrypted ICV with an ICV it calculates for the arriving payload. If both match, the frame is good (Obaidat and Boudriga 2007).

Authentication in 802.11

The 802.11 supports two authentication mechanisms: open system authentication and shared key

authentication. Open system authentication is a two-way authentication that is used when a high security level is not required. A station requesting authentication sends a request to the access point. The access point responds with a frame indicating either approval or disapproval. The shared key algorithm is based on WEP and requires the station and the access point to have a shared key. A four-way authentication process takes place, which can be described as follows:

1. Client sends authentication request to the AP.
2. AP sends back a challenge.
3. Client sends back the challenge, encrypted.
4. The AP decrypts what is received and compares it with the challenge. A match results in successful authentication.

Another authentication method that is not part of the 802.11 standard yet is implemented by many vendors is the MAC address authentication. Here, the client's MAC address is compared against a list of MAC addresses that are authorized to access the network. This process is vulnerable to device theft; thus, it should be used in combination with the other two approaches to allow for more security. The MAC address list is stored in a separate server called the RADIUS server. During the authentication process, the AP communicates with the RADIUS server to see if the latter has the MAC address in question (Obaidat and Boudriga 2007).

Vulnerabilities

It is well known that the 802.11 security mechanisms are vulnerable to all sorts of attacks. As an example, consider the shared key authentication process. The AP sends the challenge in clear text format, which exposes the authentication procedure to clear text attacks. An eavesdropper can get the challenge and the response, and from these two extract the stream key. This is easy because the encryption is a simple exclusive OR (XOR) operation between the plain text and the stream key; XORing the cipher text and the clear text gives the stream key. Using the stream key, the hacker can be authenticated easily because he/she can encrypt any challenge the AP sends. Listening to the channel and obtaining all of the information sent back and forth is very simple. All a hacker needs is a sniffing software tool, which can log all of the communications taking place on the channel.

An easier way to get the key is to make an educated guess. Remember that the keys have to be manually set up. In many cases, users do not change the key when it comes from the manufacturer, which makes guessing a simple matter of knowing the default key/keys that come from different vendors.

The IV length (24 bits) presents another security threat. Given a highly loaded network or a patient hacker, the AP will exhaust all IVs and start reusing them. The hacker can thus collect enough frames with the same IV and extract the common parts between them. This would expose the secret key along with the whole wireless LAN.

The lack of AP authentication (having the AP authenticate itself to the station) is yet another vulnerability.

A hacker passively listening on the channel for an ample amount of time can collect useful information that enables him to set up an AP. Nodes closer to this (rogue) AP will connect to it. This way, the attacker will collect valid users' information and use it to access the network. This would not be possible if the AP had to authenticate itself to the stations (Geier 2002a). Even more vulnerability has been pointed out in the research community; Geier (2002a) contains a list of such sources.

QoS SUPPORT: IEEE 802.11e

As users grow accustomed to wireless LANs, their expectations rise. Users want wireless LANs to provide the same functionality as wired counterpart. In addition, the emergence of new applications of wireless LANs—including home-office networking and wireless local loop—that require delay- and loss-sensitive multimedia communication makes QoS support an inevitable extension. Corporate wireless networks are expected to provide voice over IP (VoIP) services that can reduce or even replace the need to use cell phones in the work environment. Home networks, in which a wireless network can eliminate all the wires in a home and connect the different devices together, are another foreseeable domain. Service providers would benefit from a wireless local loop for their services; this would provide a cost-effective solution and a competitive edge.

Challenges in Providing QoS over Wireless

The wireless channel is highly dynamic. The signal strength and quality are affected by fading, self-interference, co-channel interference, and noise, among other things. In addition, nodes move in random patterns and change their access points as they do so. At the same time, energy consumption has to be minimized because the devices used (laptops, PDAs, etc.) are battery operated. These and other issues make supporting QoS over wireless a very challenging task.

As we have seen, the hidden terminal problem imposes difficulties on sensing the channel and thus represents a limiting factor of the performance of the MAC protocol. The DCF of the 802.11 uses a CSMA-based protocol, which involves back-off periods of random length. Therefore, by definition the DCF is not suitable for QoS support. The PCF, even though it was proposed to address delay-sensitive applications, was found to provide poor performance for even a small number of voice communications. This is readily apparent because the increase in the number of PCF nodes results in an increase in the polling list. Hence, nodes end up waiting for longer periods for their chance to transmit. Another problem with the PCF is its lack of different priority levels. In addition, the PCF works only in the infrastructure mode and not in the ad hoc mode. As a result, the 802.11e has been developed (IEEE 802.11e Working Group 2005).

QoS Mechanisms

The 802.11e provides QoS support using two coordination functions: the hybrid coordination function (HCF) with contention avoidance, and the HCF with polled

Table 3: ACs and Applications Addressed

AC	Applications Targeted
0	Low priority/best effort traffic
1	Video probe
2	High-rate real time (e.g., video)
3	Low-rate real time (e.g., voice)

access operation. The first is more commonly referred to as the enhanced DCF (EDCF).

Enhanced DCF

The 802.11e (both EDCF and HCF) supports four traffic classes known as access categories (AC) in the 802.11e terminology. Table 3 shows the different ACs and what applications they address. The protocol assumes the existence of a mechanism to classify the traffic. In other words, the protocol works with packets already marked with one of the four ACs.

The protocol supports the different priorities by mainly changing two parameters: the inter-frame spacing and the limits of the contention window. The traditional DCF supports priority in gaining the channel, by introducing different IFSSs for ACKs, PCF, and DCF. Similarly, the EDCF uses different IFSSs for different ACs (called arbitration IFSSs, or AIFSSs). Thus, higher-priority packets can acquire the channel before others. In addition, the size of the contention window is smaller for higher-priority packets. The smaller the contention window size, the faster a node can gain the channel. The smaller the CW_{min} , the shorter the back-off time. Furthermore, the faster a station reaches the CW_{max} , the faster it increments its retry counter, which results in faster channel gain.

In traditional DCF, a station has to contend for the channel for every packet it needs to transmit. EDCF, in contrast, allows transmission of more than one packet. The transmit opportunity (TXOP) is a parameter that defines the duration of time a station can seize the channel once access is gained.

If you have ever tried to make a phone call and heard the "all circuits are busy" message, you know what admission control is. Given the limited amount of resources available, a network can support a defined volume of traffic for every AC. If the input traffic of a particular AC exceeds its defined limit, all sources belonging to that AC will suffer. To prevent such behavior, admission control is applied. The goal of admission control is to deny access to any source attempting to use the channel once the predefined limit has been reached. The distributed admission control (DAC) scheme of the EDCF monitors channel utilization and announces that information to all stations in its beacon message. When the available resources approach zero, sources stop initiating new stream sessions.

HCF with Polled Access Operation

The HCF operation is very similar to the PCF function; it relies on polling to meet different nodes' requirements.

A logical entity called the hybrid coordinator (HC) that runs in the AP is responsible for scheduling and other processing related to the polling operation. Unlike the EDCF, in which the TXOP is predefined, the HCF provides a mechanism for stations to request a TXOP with specific characteristics. The HCF can operate in one of two modes: contention-free HCF and coexistence with the EDCF.

In the contention-free HCF, the AP polls the stations. In its poll message, the AP specifies the TXOP. A station with some traffic to send replies to the poll within a SIFS period. If the station does not have traffic or if the length of the TXOP is not sufficient, it replies with a null frame.

The HCF function can operate with both the EDCF and the DCF at the same time. To poll the stations, the AP waits for the duration of a PIFS time, which is shorter than what a DCF or EDCF station needs to wait for. Thus, the AP can gain the channel. Similarly, a polled station has to wait only for the duration of a SIFS time to respond to a poll. Therefore, the HCF function can work smoothly during the contention period of EDCF or DCF.

Although the EDCF has the logic to indicate whether new traffic should be initiated, it does not enforce any type of behavior on the nodes. The AP simply announces the available capacity. Honoring this information (or not) is completely up to the stations. The HCF, on the other hand, has a strict admission control mechanism. A station willing to initiate a stream has to consult with the AP, which determines whether the stream can be supported without affecting other streams. Stations communicate to the AP the QoS parameters they desire using the transmission specification (TSPEC). In the TSPEC, a station specifies the priority, data rate, delay, and frame size, among other parameters. The AP checks these requirements against the current network conditions and decides accordingly whether to honor the request, reject it, or provide the station with TSPEC that it can afford to support (i.e., renegotiate the requirements). The station may accept the offer or turn it down. A station is removed from the pollable list either when it explicitly deletes the TSPEC or when the TSPEC timer expires. The timer expires when the station sends a null frame for a number of poll requests within a defined time interval defined by the TSPEC timer.

ADVANCED TOPICS

Bluetooth

Bluetooth is a low-power (1 mW), short-range (within 10 m) technology. It was initially proposed by Ericsson as a way to use laptops for making phone calls over a cell phone. The technology has been adopted by many companies and for different applications, primarily with regard to cable replacement and ad hoc networking (intercommunication between Bluetooth-enabled devices). Like WLANs, Bluetooth works in the ISM band, which is the reason it uses the high rate frequency-hopping scheme.

A Bluetooth network is organized into piconets and scatternets. A piconet is a small network consisting of a master node and a number of slaves (between one and seven). The master node is responsible for choosing the communication channel, including frequencies and

the hopping sequence used. Nodes in a piconet communicate through the master node and not directly. A node may belong to one or more piconets. This overlapping creates what is called a scatternet. The latter allows for multihop communication in which overlapping nodes serve as forwarders from one piconet to another.

The protocol consists of the following five layers, which are responsible for link establishment and maintenance, security and error control, service discovery, and communication with higher-layer protocols (Stallings 2002; Nicopolitidis et al. 2003):

1. Radio layer: This layer deals with the specifications of the air interface. Frequency bandwidth, modulation, transmission power, and channel access are specified. The standard specifies the use of GFSK for modulation. It also specifies the use of FHSS operating in a 78 MHz bandwidth with each channel occupying 1 MHz. The hopping rate is equal to 1600 hops/sec and a maximum data rate of 1 Mbps.
2. Baseband layer: This layer specifies how FHSS with TDD/TDMA is to be used for communication between nodes in a piconet. To prevent interference, nodes in different piconets use CDMA (i.e., different piconets use different hopping sequences). Two types of communication can be used. The synchronous connection-oriented (SCO) type is used for communication between a slave and a master and involves the allocation of fixed bandwidth. The asynchronous connectionless (ACL) type is a point-to-multipoint communication between the master and all of the slaves in a piconet.
3. Link manager protocol (LMP): As its name implies, this protocol specifies link setup and management between two Bluetooth devices. Issues include clock synchronization, authentication and key distribution for security purposes, the protocol version used, the nodes' mode (master or slave), and so forth.
4. Logical link control and adaptation protocol (L2CAP): This protocol defines connection-less as well as connection-oriented services. It also allows for QoS support by letting a transmitter and a receiver negotiate QoS flow parameters such as delay and delay variation.
5. Service discovery protocol (SDP): This protocol specifies how Bluetooth devices search for other Bluetooth devices and establish communication with them.

One domain in which Bluetooth is envisaged to serve greatly is home networking. Connectivity between different devices at home that serves both coordination and cable freedom will provide more user-friendly technology.

Voice over 802.11

Although wireless LANs were initially thought of as wireless versions of a wired LAN, which implies that they are solely for data communications, the fact that they are wireless introduces higher expectations. Voice over WLAN provides one such example. Even though cellular networks allow voice communications while users are on the move, a common network used for both voice and data costs less than operating two separate networks—one for data and one for voice.

As we have seen, 802.11 DCF is the fundamental access method of the 802.11 and is used for data communications. It uses CSMA/CA for channel access with a back-off algorithm to reduce the possibility of collisions. Although DCF was meant for data communications, studies have shown that it can be used for voice. However, the performance is relatively low (Prasad 1999). Because it is a random assignment scheme, DCF provides unbounded delays for high loads. Randomness means that the network cannot provide deterministic guarantees regarding delay. It is important to mention that delay and delay variation (jitter) are the key impairments for voice communications (Obaidat and Obeidat 2002; McDysan and Spohn 1999).

The inability of CSMA protocols to support real-time traffic has been studied in the context of voice/data integration over the Ethernet. It has been shown that the Ethernet can provide good performance at low loads. Moreover, it has been argued that the need for priority in WLANs is more pressing than in Ethernet for the following reasons:

1. WLANs provide lower rate than the Ethernet, which results in high queuing and transmission delays.
2. CSMA/CA has worse throughput/delay characteristics than CSMA/CD.

The PCF is used for real-time traffic that has delay bounds. However, it can operate only under the centralized scheme where there is a base station, because PCF uses polling to grant stations channel access. A lot of research has addressed the performance of voice and data over the PCF function of the IEEE 802.11. The performance of voice and data over the PCF function was studied with the assumption that voice communication takes place between stations that are in different basic service sets. The conclusion reached was that the performance of the PCF function was poor and only a few voice conversations could be supported. No echo cancellation was used; therefore, a small superframe size of 20 ms, which limits how many conversations can be in the polling list, was considered.

Crow et al. (1997b) propose the use of echo cancellation for voice communication. However, they use a 420 ms superframe size that consumes most of the delay budget of voice. This implies that if voice goes through an IEEE 802.11 link, it has to be the only link. In other words, the wireless link cannot be the last hop in the path between the source and the destination of the call. The authors suggest that when a voice station does not have any data to transmit or receive, it should be dropped from the polling list immediately. This way, the remaining bandwidth can be used by other stations. Nonetheless, leaving the list every time a station's silence period starts (i.e., the voice source is in the OFF state) will result in more delay at the beginning of every talk spurt, which will not be acceptable.

The performance of noncompressed voice (64 kbps) and data over IEEE 802.11 has been studied using an analytic approach. The conclusion is that the performance is low; with the introduction of echo cancellation, more voice conversations can be achieved, but this will affect the bandwidth available to the data stations. One recommendation for dealing with voice traffic is not to drop a

voice station from the polling list, even when it is silent. Although this will limit the number of voice communications, it will control delays and delay variations, resulting in a reasonable number of voice conversations.

All of the aforementioned studies use the same PCF parameters that trade one thing for another. The key parameters here are the superframe size and the packet size. However, all of the studies concluded that voice performance over PCF is poor. A comparison between the performance of DCF and EDCF for voice, video, and data is provided in Choi et al. (2003). It is shown that EDCF provides better performance in terms of frame loss and delay for voice. However, PCF is not considered in the comparison.

CONCLUSION

This chapter introduces the reader to WLANs. It begins by providing the motivation and applications of WLANs. The most well-known WLAN standards, IEEE 802.11 and ETSI HIPERLAN, are explored. The main coordination functions (DCF and PCF) are defined, and their pros and cons are explained. Moving to the physical layer, FHSS, DSSS, and IR transmission schemes are presented, as are the a, b, and g versions of the IEEE 802.11 physical layer standard. Following the basic information, we explore issues of QoS and security in 802.11 context. We conclude the chapter by presenting some advanced related topics, such as the Bluetooth networks and the voice over 802.11 systems.

GLOSSARY

- AC:** Access categories; supported by the IEEE 802.11e standard in order to provide quality of service.
- ACH:** Access feedback channel; a time channel used in the MAC protocol of the HIPERLAN 2 standard. This is a downlink channel used by the AP to inform stations of previous random access attempts.
- ACK:** Acknowledgement packet transmitted by the destination node to the source node in order to acknowledge the successful reception of a data packet.
- ACL:** Asynchronous connectionless; in a Bluetooth network, this is a point-to-multipoint communication between the master and all of the slaves in a piconet.
- Ad hoc network:** A network topology in which there is no central control (base station or access point) and the stations are able to communicate directly.
- AP:** Access point; a station responsible for providing central control in a network cell.
- ATM:** Asynchronous transfer mode; a network technology based on transferring data in cells or packets of a fixed size.
- Authentication:** The process of identifying an individual, usually based on a username and password.
- Band:** A contiguous range of frequencies.
- BCH:** Broadcast channel; a downlink channel through which the AP sends control information to all nodes in a HIPERLAN 2 network.
- Block Ciphers:** An encryption type in which the plain text is divided into blocks, and each block is encrypted using a fixed-size stream key.

- Bluetooth:** A low-power (1 mW), short-range (within 10 m) wireless network technology.
- BRAN:** Broadband radio access network; an ETSI project that standardizes the wireless ATM protocols, including HIPERLAN types 2, 3, and 4.
- BSA:** Basic service area; the coverage area of a BSS.
- BSS:** Basic service set; resembles the basic building block in the 802.11 architecture. This is analogous to a cell in a cellular network.
- Carrier:** A waveform in a communications channel modulated to carry analog or digital signal information.
- CCK:** Complimentary code keying; a modulation technique used in the IEEE 802.11b standard. Using the CCK modulation, every 4 bits from the data stream are encoded in an 8-chip code, thus allowing for a data rate equal to 5.5 Mbps.
- CDMA:** Code division multiple access; a technique used to prevent interference among different nodes that transmit simultaneously along the same frequency band.
- CFP:** Contention-free period; a time interval defined by the PCF access mode.
- Chip:** A chip sequence is used to replace a data bit in the IEEE 802.11 standard.
- Coding Techniques:** Allow for maximizing the benefit of transmission over noisy wireless channels by introducing redundancies in the bits transmitted so that the receiver can still recover a reasonably distorted packet.
- Collision:** The situation that occurs when two or more nodes attempt to send a signal along the same channel at the same time. The result of a collision is generally a garbled message. All computer networks require some sort of mechanism to either prevent collisions altogether or recover from collisions when they do occur.
- Contention-based Protocol:** A MAC protocol type, in which nodes contend to gain access to the channel.
- Contention-free Protocol:** A MAC protocol type, usually used in infrastructure network topology, which states that the nodes do not contend for medium access; instead, there is a central control that decides which node can transmit.
- CSMA/CA:** Carrier sense multiple access with collision avoidance; a MAC protocol used by the IEEE 802.11 standard.
- CSMA/CD:** Carrier sense multiple access with collision detection; a MAC protocol used by the IEEE 802.3 (Ethernet) networks.
- CTS:** A clear-to-send packet is transmitted to the source node by the destination node in a IEEE 802.11 WLAN to show that it ready to receive data.
- CW:** Contention window; a time interval that defines the range of the back-off time in an IEEE 802.11 WLAN.
- DBPSK:** Differential binary phase shift keying; in an IEEE 802.11 WLAN, the DSSS physical layer uses this modulation technique in which every symbol carries one bit, allowing for a data rate of 1 Mbps.
- DCF:** Distributed coordination function; a contention-based protocol that resembles the basic access mode of the 802.11 standard. It is based on the CSMA/CA scheme and assumes an ad hoc network topology.
- DIFS:** Distributed coordination function IFS; the time delay used by DCF frames.
- Directional Antennas:** Focus their radiation in one direction to provide greater coverage distance.
- Diversity Antennas:** Receive on more than one element; when transmitting, they send through the element with the best received signal.
- DQPSK:** Differential quadrature phase shift keying; in order to support data rate of 2 Mbps in an IEEE 802.11 WLAN, this modulation technique is used in which every symbol carries two bits from the data stream.
- DSSS:** Direct sequence spread spectrum; a physical layer protocol used by IEEE 802.11. The main idea of DSSS is to spread the signal energy over a large bandwidth so that the signal can be treated as noise that can be easily rejected by unintended receivers.
- ECD:** Electronic codebook; any encryption algorithm that generates the same cipher text every time it is fed the same plain text.
- EDCF:** Enhanced DCF; this protocol is used by the IEEE 802.11e standard. It uses traffic categories to support QoS.
- ESS:** Extended service set; multiple BSSs can be connected to one another by connecting their APs to a distribution system, forming this service set.
- ETSI:** European Telecommunications Standards Institute.
- Exposed Terminal:** This problem can appear in an ad hoc WLAN topology. Specifically, a node postpones its transmission because it wrongly estimates that its data will collide.
- EY-NPMA:** Elimination yield-non-preemptive multiple access; this protocol is a contention-based MAC protocol used by the HIPERLAN 1 standard.
- FCC:** Federal Communications Commission; main duty is to regulate public airwaves in the United States.
- FCH:** Frame control channel; a downlink channel that is used by the AP to announce how the rest of the current MAC frame has been allocated. This is used by the HIPERLAN 2 WLAN standard.
- FEC:** Forward error control; increases the throughput by minimizing the need for retransmissions of bad packets (used by HIPERLAN).
- FHSS:** Frequency hopping spread spectrum; a signal is spread by sending at one frequency for a short period of time and then switching (hopping) to another frequency in a seemingly random fashion. This is a physical layer protocol used by the IEEE 802.11 standard.
- GFSK:** Gaussian frequency shift keying; according to the IEEE 802.11 standard, the PMD sublayer modulates data using this technique. Depending on the data rate supported (1 Mbps or 2 Mbps), either GFSK or 4 GFSK is used. 4GFSK translates every 2 bits into one signal element, allowing for double the rate.
- GMSK:** Gaussian minimum shift keying; this modulation scheme is used by the HIPERLAN/1 standard.
- HCF:** Hybrid coordination function; a QoS supportive protocol used by the IEEE 802.11e standard.
- HEC:** Header error control; an ITU-T cyclic redundancy check, CRC16 used for error detection by the IEEE 802.11 standard.

Hidden Terminal: This problem can appear in an ad hoc WLAN topology using carrier sense. Specifically, a node's transmission collides because it is not able to detect the transmission of another node.

HIPERLAN: High performance local area network; a WLAN standard defined by ETSI.

HR-DSSS: High-rate DSSS; defined by 802.11b, this service set allows data rates as high as 5.5 Mbps and 11 Mbps.

IBSS: Independent basic service set; resembles the infrastructure-less ad hoc arrangement. In an IBSS, stations communicate in a peer-to-peer fashion in which no AP or other intermediary is needed. At least two stations are needed to form an IBSS.

IFS: Inter-frame spacing; in an IEEE 802.11 WLAN, access priority to the wireless channel is provided by this spacing, which is the duration of time that has to pass before an attempt is made to access the channel.

Infrastructure Topology: A network topology in which the medium access is controlled centrally (using a base station or access point).

Interference: Refers to the extraneous, unwanted signals that affect the proper system operation. Not only does interference affect the quality of the signal communicated from the transmitter to the receiver; it can also affect the functionality of the protocol.

IR: Infrared.

ISI: Intersymbol interference; this problem results when a symbol takes too long to reach the receiver. This delay, called delay spread, results from multipath propagation. Because of this delay, a symbol may arrive at the same time as another subsequent symbol.

ISM: Industrial, scientific, and medical band; a frequency band that does not require any licensing; thus, it is used by many wireless applications.

L2CAP: Logical link control and adaptation protocol; used by the Bluetooth standard and defines connection-less and connection-oriented services. It also allows for QoS support by letting a transmitter and a receiver negotiate QoS flow parameters such as delay and delay variation, among other things.

LMP: Link manager protocol; specifies link setup and management between two Bluetooth devices. Issues include clock synchronization, authentication and key distribution for security purposes, the protocol version used, the nodes' mode (master or slave), and so forth.

MAC: Medium access control.

Modulation Techniques: Techniques used to modulate the data stream into a form suitable for physical transmission.

Multipath Fading and Shadowing: When a signal is transmitted, multiple versions of the same signal take different paths to reach the receiver. The first to arrive at the receiver is the one that goes through the line of sight (LOS), which is the path that does not have any obstacles between the transmitter and the receiver. Other, delayed versions follow other paths that result from impinging on obstacles in the path. When these delayed copies arrive, they either add constructively or destructively to the receiver. This phenomenon, in which the signal quality depends on the multipath propagation, is referred to as multipath fading.

NAV: Network allocation vector; in an IEEE 802.11 network, every node maintains this vector. Nodes adjust the values of their vectors as they overhear packet transmissions. A node attempts to check the channel status (whether idle or not) only when the duration in the NAV elapses.

OFDM: Orthogonal frequency division multiplexing; according to the IEEE 802.11a standard, the data are modulated using this scheme. OFDM breaks the channel bandwidth into subchannels. Each subchannel has a low symbol rate and thus low ISI. The subchannels are chosen to be orthogonal; as a result, low co-channel interference occurs.

Omnidirectional Antennas: Provide a 360-degree radiation pattern.

Path Loss: As a signal propagates from the transmitter to the receiver, it attenuates (i.e., loses its energy) with distance. This phenomenon is called path loss. It depends on many other factors as well, including the reflecting objects and big obstructions in the path between the transmitter and the receiver.

PBCC: Packet binary convolutional coding; a modulation technique used in the IEEE 802.11b standard. Using this modulation, every 8 bits from the data stream are encoded in an 8-chip code, thus allowing for a data rate equal to 11 Mbps.

PCF: Point coordination function; provides a contention-free protocol that can be used for connection-oriented real-time traffic such as voice in an IEEE 802.11 network. This is done by polling the stations one at a time using the access point.

PIFS: PCF inter-frame space; in an IEEE 802.11 network, this is the short time interval that the AP has to wait in order to gain access to the channel before any other node.

PLCP: Physical layer convergence protocol; an 802.11 sublayer protocol responsible for adding necessary headers for the purposes of synchronization, timing, and error control.

PLW: PSDU length word; a 12-bit field that indicates the size of the MAC frame used by the physical layer of the IEEE 802.11 standard.

PMD: Physical medium dependent; this sublayer is responsible for raw transmission of bits over the air; mainly performs modulation of the data stream. It is defined by the IEEE 802.11 standard.

PSF: PLCP signaling field; a 4-bit field used to specify the data rate at which a frame was transmitted. Data rates range from 1 Mbps to 4.5 Mbps in increments of 0.5 Mbps. This is defined by the IEEE 802.11 standard.

QoS: Quality of service.

RC4: A stream cipher encryption algorithm that uses symmetrical keys.

RCH: Random access channel; an uplink channel used by the nodes to compete for slots in subsequent MAC frames. This is used by the HIPERLAN/2 MAC protocol.

RTS: Request to send; in an IEEE 802.11 WLAN, this control packet is initially transmitted by the source node to the destination node to obtain permission to transmit data.

- SCO:** Synchronous connection oriented; in a Bluetooth network, this is a communication between a slave and a master that involves the allocation of fixed bandwidth.
- SDP:** Service discovery protocol; specifies how Bluetooth devices search for other Bluetooth devices and establish communication with them.
- SIFS:** Short IFS; according to the IEEE 802.11 MAC protocol, this is the shortest amount of time and hence the highest priority, followed by the PIFS and the DIFS.
- Stream Ciphers:** In a stream cipher encryption algorithm, the data stream is processed continuously (e.g., one byte at a time).
- TDD:** Time division duplexing; the main idea of this protocol is that part of the frame is used for the uplink and part is used for the downlink.
- TDMA:** Time division multiple access; in this scheme, stations are dynamically assigned time slots according to their needs.
- TSPEC:** Transmission specification; in an IEEE 802.11e network, stations communicate the QoS parameters they desire to the AP using this method. In the TSPEC, a station specifies the priority, data rate, delay, and frame size, among other things.
- UNII:** Unlicensed National Information Infrastructure; a 5GHz frequency band used by IEEE 802.11a and the HIPERLAN networks.
- WEP:** Wired equivalent privacy; the 802.11 standard uses this protocol, which is based on the RC4 encryption algorithm. A better and more secure protocol—called Wi-Fi protected access (WPA)—was released recently.
- WLAN:** Wireless local area network.

INTRODUCTION

Wireless networks can be classified in many ways based on mobility, topology, application, or coverage. For example, using mobility, we may classify wireless networks as fixed, stationary, portable, or mobile. If we consider applications, we may look at wireless data networks and cellular voice networks. The topology of a wireless network may be based on a fixed infrastructure that enables a *mobile station* (MS) to connect to the rest of the network or the topology may be ad hoc where MSs connect to one another in a peer-to-peer manner without assistance from a fixed infrastructure. Typically in the former case, a wired distribution system that connects points of access (e.g., base stations or access points) to the fixed network is assumed. If the points of access can connect to one another using an air interface, then a mesh topology is also possible. The most popular classification is based on coverage: whether the wireless network provides service over a local area or a larger geographical region. *Wireless local area networks* (WLANs) typically cover areas ranging anywhere between parts of a building to the campus of an organization. *Wireless wide area networks* (WWANs) cover entire cities and even parts of a nation. Usually, WWANs provide lower data rates compared to WLANs and are more complex in architecture. The spectrum allocated to WWANs is typically licensed spectrum and there needs to be careful planning and deployment of WWANs. WLANs mostly form extensions to existing *local area network* (LAN) segments in organizations. They typically use unlicensed spectrum and as long as the interference is reasonable, they can be deployed by anyone, anywhere. Currently, WLANs are also being used to provide broadband Internet access in hot spots such as airports, cafes, and hotels.

There are several standards for WWANs and WLANs, and they are primarily dependent on geography. The European Telecommunications Standards Institute (ETSI) based in France is responsible for the standards activities in the European Union although these standards have been sometimes adopted in other parts of the world. In the United States, standards activities are less centralized. There are many organizations involved in standards activities such as the Institute for Electrical and Electronic Engineers (IEEE), American National Standards Institute, the Telecommunications Industry Association, and so on. Typically, a standard is created based on input from several industry groups; once such standards are approved, the International Standards Organization often adopts these standards (see Box 1 for a list of URLs for standards bodies). Many of the details in this article are derived from the IEEE 802.11 standards and information available on the IEEE 802.11 Web site.

Standards for wireless technologies must deal with a gamut of different issues, starting from the spectra that can be used by this technology and going up to defining entities in the system and the detailed protocols between them. In this chapter, we will briefly look at wireless local area network standards in general and focus on one particular WLAN standard—namely, the IEEE 802.11 standard.

WLAN Standards

Standards activities for WLANs have evolved geographically with ETSI's broadband radio access network working on *high-performance radio LAN* (HIPERLAN) standards in Europe and the IEEE on the 802.11 series in the United States. In Japan, the Multimedia Mobile Access

Communications Promotion Council working group under the Association of Radio Industries and Businesses works on WLAN standards. The spectra used by WLANs is mostly unlicensed, although some systems use licensed spectra as well (e.g., HIPERLAN in some licensed bands). The only commercially successful WLAN standard has been the IEEE 802.11. HIPERLAN/1 was standardized in the mid 1990s and supported complex multihop ad hoc networking. The medium access mechanism in HIPERLAN/1 (Wilkinson, Phipps, and Barton 1995) was based on a form of carrier sense multiple access called *elimination-yield nonpreemptive multiple access* (EY-NPMA). HIPERLAN/2 has adopted a physical layer that is very similar to IEEE 802.11a and a medium access mechanism based on reservation and TDMA. However, both these standards have not been adopted successfully

in commercial products. The MMAC activities include a variety of wireless access networks (some compatible with the IEEE 802.11 standards) ranging from wireless personal area networks to outdoor fixed public networks. Recently, there have been efforts to harmonize the standards activities of ETSI, IEEE 802.11, and MMAC. Table 1 summarizes some of the 802.11, HIPERLAN, and MMAC standards. In the rest of this chapter, we will consider primarily the IEEE 802.11 standard in some detail.

INTRODUCTION TO THE IEEE 802.11 STANDARD

Within the IEEE, several standards activities are carried on by different groups. The IEEE 802 LAN/MAN standards committee is responsible for local area network standards and *metropolitan area network* (MAN) standards. Individual working groups are in charge of a variety of LAN/MAN standards, of which the 802.11 working group is responsible for WLAN standards.

Like most LAN standards, the 802.11 standard (Crow et al. 1997) is concerned only with the lower two layers of the open system interconnection OSI stack—namely, the physical (PHY) and MAC layers. The MAC and PHY layers operate under the IEEE 802.2 logical link control layer, which supports many other LAN protocols. In the case of wired LAN standards such as 802.3, several physical layers correspond to the same MAC specifications. A good example is IEEE 802.3, which was originally designed for thick coaxial cable but was subsequently revised to include thin coaxial cable, a variety of twisted pair cables, and even fiber-optic links. In the same way, the IEEE 802.11 standard specifies a common MAC protocol that is used over many different PHY standards. The PHY standards are the “base” IEEE 802.11 standard, the 802.11b and g standards, and the 802.11a standard. A new 802.11n physical layer is under consideration by the 802.11 working group. The MAC protocol is based on *carrier sense multiple access with collision avoidance* (CSMA/CA). An optional polling mechanism called *point coordination*

Table 1: Summary of Some WLAN Standards

Standard	Standards Body	Spectrum	Data Rate	Primary Medium Access	Primary Region
IEEE 802.11, b, g	IEEE	2.4-GHz ISM bands	1, 2, 5.5, 11, up to Mbps	CSMA/CA ¹	North America
IEEE 802.11a	IEEE	5-GHz UNII and ISM bands	Up to 54 Mbps	CSMA/CA	North America
IEEE 802.11n ²	IEEE	2.4-GHz ISM bands	> 100 Mbps	CSMA/CA	North America
HIPERLAN/1	ETSI	5-GHz bands	23 Mbps	EY-NPMA ³	Europe
HIPERLAN/2	ETSI	5-GHz bands	Up to 54 Mbps	TDMA reservation	Europe
Wireless access and WLAN	MMAC	3–60 GHz bands	20–25 Mbps	Various	Japan

²The IEEE 802.11n standard is yet to be finalized

³Elimination yield nonpreemptive multiple access

Figure 1: Protocol stack of IEEE 802.11

function (PCF) is also specified. In addition to the MAC and PHY layers, the IEEE 802.11 standard also specifies a management plane that transmits management messages over the medium and can be used by an administrator to tune the MAC and PHY layers. The *MAC layer management entity* (MLME) deals with management issues such as roaming and power conservation. The *PHY layer management entity* (PLME) assists in channel selection and interacts with the MLME. A *station management entity* handles the interaction between these management layers. Figure 1 shows the protocol stack associated with IEEE 802.11.

The base IEEE 802.11 standard specifies three different PHY layers: Two use *radio-frequency* (RF), and one uses *infrared* (IR) communications. The RF PHY layers are based on *spread spectrum* (SS): either *direct sequence* (DS) or *frequency hopping* (FH). The IR PHY layer is based on *pulse position modulation* (PPM). Two different data rates are specified: 1 and 2 Mbps for each of the three PHY layers. The RF physical layers are specified in the 2.4-GHz *industrial, scientific, and medical* (ISM) unlicensed frequency bands.

The IEEE 802.11b standard specifies the physical layer at 2.4 GHz for higher data rates: 5.5 Mbps and 11 Mbps. The PHY layer makes use of a modulation scheme called *complementary code keying* (CCK). The transmission rate depends on the quality of the signal, and it is backward-compatible with the base 802.11 standard, which is based on the *direct sequence spread spectrum* (DSSS). Depending on the signal quality, the transmission rates could fall back to lower values. The 802.11g standard further increases the data rates to as much as 54 Mbps in the 2.4-GHz ISM bands using *orthogonal frequency division multiplexing* (OFDM). The IEEE 802.11a standard (Kapp 2002) deals with the PHY layer in the 5-GHz *unlicensed national information infrastructure* (UNII) bands. Once again, data rates as high as 54 Mbps are specified in these bands with OFDM as the modulation technique. Depending on the PHY layer alternative, the frequency band is divided into several channels. Each channel supports the maximum data rate allowed by that PHY layer alternative. The proposal for an especially high rate PHY layer (>100 Mbps) called *802.11n* employs multiple input and output antennae at the transceivers. The technology is popularly called *multiple-input multiple-output* (MIMO) and also uses OFDM as the modulation scheme.

In the next few sections, the IEEE 802.11 standard is discussed in a top-down manner. First, the different topologies possible in IEEE 802.11 are considered with the focus on understanding some of the management

functions. Then detailed discussions of the MAC layer of 802.11 and different PHY layer alternatives are presented. Once the basic operation of the 802.11 WLAN has been considered, security issues in IEEE 802.11 will be discussed, as will recent ongoing activities to extend the standard further.

IEEE 802.11 WLAN OPERATIONS

The topology of an IEEE 802.11 WLAN can be one of two types: infrastructure or ad hoc (see Figure 2). In the infrastructure topology, an *access point* (AP) covers a particular area called the *basic service area* (BSA), and mobile stations communicate with each other or with the Internet through the AP (Crow et al. 1997). The AP is connected to a LAN segment and forms the point of access to the network. All communications go through the AP. So an MS that wants to communicate with another MS first sends the message to the AP. The AP looks at the destination address and sends it to the second MS. The AP, along with all of the MSs associated with it, is called a *basic service set* (BSS). In the ad hoc topology (also called *independent BSS* or IBSS), MSs that are in range of each other can communicate directly without a wired infrastructure. However, it is not possible for an MS to forward packets meant for another MS that is not in the range of the source MS. Figure 2 shows schematics of both topologies. MSs and APs are identified by a 48-bit MAC address that is similar to other MAC addresses at the link layer. In an infrastructure topology, the MAC address of the AP also forms the *BSSID*, a unique identifier of the BSS.

Figure 2: Topologies in IEEE 802.11

If we assume that the range of communication of any WLAN device—be it an MS or an AP—is a region of radius R , then we can look at the comparative advantages of the two topologies. An MS can communicate with another MS that is as far as $2R$ away using an AP, provided both MSs are within a distance R of the AP. The cost here is the additional transmission from the AP to the destination. In the ad hoc topology, a destination MS cannot be more than a distance R from the source MS. The advantage is that the information can be received in one hop.

Extending the Coverage in Infrastructure Topology

Depending on the environment in which it is deployed and the transmit powers that are used, an AP can cover a region with a radius anywhere between 30 feet and 250 feet. The coverage depends on radio propagation characteristics in the environment and the antenna features (Pahlavan and Krishnamurthy 2002). The presence of obstacles such as walls, floors, equipment, and so on can reduce the coverage. Many new 802.11-equipped devices have integrated antennae that additionally reduce coverage. To cover a building or a campus, it often becomes necessary to deploy multiple APs that are connected to the same LAN. A group of such APs and the member mobile stations is called an *extended service set* (ESS). The coverage area is called the extended service area. The wired backbone that connects the different APs along with services that enable the ESS is called the *distribution system*. The distribution system, for example, supports roaming between APs so that MSs can access the network over a wider coverage area than before. This is similar to cellular telephone systems in which multiple base stations provide coverage to a region, each base station covering only a cell. Note, however, that cellular telephone systems have a far more complex infrastructure to handle roaming and handoff. In 802.11 WLANs, it is easy to roam within a single LAN but it requires support from higher layers (such as mobile IP) to roam across different LANs.

Network Operations in an Infrastructure Topology

When an MS is powered up and configured to operate in an infrastructure topology, it can perform a passive scan or an active scan. In the case of a passive scan, the MS simply scans the different channels to detect the existence of a BSS. The existence of a BSS can be detected through beacon frames that are broadcast by APs pseudo-periodically. The reason why it is called *pseudo-periodic* is that the beacon is supposed to be transmitted regularly at certain intervals. However, the AP cannot preempt an ongoing transmission to transmit a beacon. When we discuss the MAC layer, we will see that any device has to wait for the medium to be free before transmitting a frame. If the medium is busy, the AP will transmit the beacon after the medium becomes free, in which case the beacon may not be precisely periodic. The beacon is a management frame that announces the existence of a network. It contains information about the network: the BSSID and

the capabilities of the network (the PHY alternatives it supports, if security is mandatory, whether the MAC layer supports polling, the interval at which beacons are transmitted, timing parameters, and so on). The beacon is similar to certain control channels in cellular telephone systems: for instance, the broadcast control channel (BCCH in GSM). The MS also performs signal strength measurements on the beacon frame. In the case of an active scan, the MS already knows the ID of the network that it wants to connect to. In this case, the MS sends a probe request frame on each channel. APs that hear the probe request respond with a probe response frame that is similar in nature to the beacon. In either case, the MS can create a scan report that provides it with information about the available BSSs, their capabilities, their channels, timing parameters, and other information. The MS makes use of this information to determine a compatible network that it can associate itself with.

To associate itself with an AP, the MS must authenticate itself if this is part of the capability of the network (we will look at this in a later section). Otherwise, as long as the MS satisfies the announced capabilities of the network, it can send an association request frame to the AP. The association request informs the AP of the intention of the MS to join the network; it also provides additional information about the MS such as its MAC address, how often it will listen to the beacon (called the *listen interval*), the supported data rates, and so on. If the AP is satisfied with the capabilities of the MS, then it will reply with an association response frame. In this message, the MS is given an association ID, and this frame confirms that the MS is now able to access the network. During this association phase, the MS can be authenticated by the network and vice versa. Unlike the ad hoc mode of operation, administrators can control access to the network in the infrastructure mode of operation.

If a mobile station moves across BSSs or out of coverage and returns to the BSA of an AP, then it will have to reassociate itself with the AP. For this purpose, it will use a reassociation request frame that is similar in form to the association request frame, except that the MAC address of the old AP will be included in the frame. The AP will respond with a reassociation response frame. An MS moving from one BSS to another will have to detect the drop in signal strength from the old AP and detect the beacon of the new AP before the reassociation request. It could also use a probe request message instead of detecting the beacon from the new AP. This simple handoff between two APs is MS-initiated. In cellular telephone systems, the MS is instructed by entities in the network (such as base station controllers) to perform the handoff from one base station to another. They may, however, use information supplied by the MS such as the signal strength from different base stations.

Power management is an important component of network operations in an IEEE 802.11 WLAN. When MSs have no frames to send, they can enter a sleep mode to conserve power. If an MS is sleeping when frames arrive at an AP for it, the AP will buffer such frames. A sleeping MS wakes up periodically and listens to the beacon frames. How often it wakes up is specified by the listen interval mentioned earlier. The beacon frame also contains

a field called the *traffic indication map* (TIM). This field contains information about whether packets are buffered in the AP for a given MS. If an MS detects that it has frames waiting for it, it can wake up from the sleep mode and receive those frames before going back to sleep. The MS uses a power-save poll frame to indicate to the AP that it is ready to receive buffered frames.

If the MS chooses to leave the network or shut down, it will send a dissociation frame to the AP. This frame will terminate the association between the MS and the network, enabling the network to free resources that were previously reserved for the MS (such as the association ID, buffer space, etc.).

Network Operations in an Ad Hoc Topology

In an ad hoc topology, there is no fixed AP to coordinate transmissions and define the BSS. An MS that operates in ad hoc mode will power up and scan the channels to detect beacons from other MSs that may be in the vicinity and that may have set up an IBSS. If it does not detect any beacons, then it may declare its own network. If it does detect a beacon, then the MS can join the IBSS in a manner similar to the process in the infrastructure topology. MSs in an IBSS may choose to rotate the responsibility of transmitting a beacon. Power management works in a similar way except that the source MS itself has to send an *announcement traffic indication map* frame to the recipient MS.

Network Operations in Mesh Topology

Recently, wireless mesh networking has received a lot of attention because it enables the deployment of wireless networks over a large area without the need for an extensive fixed (wired) infrastructure. A wireless mesh network consists of entities that connect to each other over an air interface and relay packets in the network thus created. This eliminates the need for a wired backbone to relay packets. Some of these entities may act like APs, creating infrastructure WLANs and becoming points of access to the mesh network. Other entities will connect to the Internet and enable any device in the mesh network to access the Internet. Wireless mesh networks can use a variety of technologies such as IEEE 802.16 or WiMAX-based devices or IEEE 802.11-based devices. In 2004, a task group “S” of 802.11 was set up to investigate mesh networking with 802.11 and propose a standard for using a wireless distribution system unlike the wired distribution system in the ESS. Although the standard is not finalized, some elements of operations in a mesh network have been proposed (Lee and Zheng 2006). In a mesh network, APs (or MSs) are required to be able to relay packets to one another using the air interface so that packets may be delivered from a source MS to a destination MS through multiple wireless hops. Entities with relay capabilities are called *mesh points*. A mechanism for determining a path from one mesh point to another is also necessary, and it is expected to be implemented at the MAC layer. Mesh portals enable connectivity to other mesh networks, LANs, or the Internet. Multicast and broadcast capability at the MAC layer is also another aspect that the IEEE 802.11s standard is expected to address.

THE IEEE 802.11 MAC LAYER

Mobile stations in an IEEE 802.11 network have to share the transmission medium: air. If two MSs transmit at the same time and the transmissions are both in range of the destination, then they may collide, resulting in the frames being lost. The MAC layer is responsible for controlling access to the medium and ensuring that MSs can access the medium in a fair manner with minimal collisions. The medium access mechanism is based on carrier sense multiple access, but there is no collision detection—unlike the wired equivalent LAN standard (IEEE 802.3). Collisions are extremely hard to detect in RF because of the dynamic nature of the channel. Detecting collisions also incurs difficulties in hardware implementation because an MS has to be transmitting and receiving at the same time. Instead, the strategy adopted is to avoid collisions to the extent possible. In IEEE 802.11, there are two types of carrier sensing: (1) physical sensing of energy in the medium and (2) virtual sensing. *Virtual sensing* is implemented by decoding a duration field in the 802.11 frame that allows an MS to know the time for which a frame will last. This time is stored in a *network allocation vector* (NAV) that counts down to zero to indicate when the medium is free again. To illustrate the IEEE 802.11 MAC layer, we will use the ad hoc topology as an example. However, the procedures are identical in an infrastructure topology as well.

The Distributed Coordination Function

We will first describe the basic medium access process in IEEE 802.11 called the *distributed coordination function* (DCF). Consider Figure 3 that shows the basic method for accessing the medium in IEEE 802.11. A MS will initially sense the channel before transmission. If the medium is free, the MS will continuously monitor the medium for a period of time called the *DCF interframe space* (IFS), or DIFS. If the medium is still idle after DIFS, then the MS can transmit its frame without waiting. Otherwise, the MS will enter a backoff process. The rationale is that if another MS senses the medium after the first MS, then it will also wait for DIFS. However, before a time DIFS expires, the first MS would have started its transmission. On hearing the transmission, the second MS will have to back off. The wireless medium is harsh and unreliable, hence all transmissions are acknowledged. The destination of the frame will send an *acknowledgement* (ACK) back to the source if the frame is successfully received as follows. It will wait for a time called the *short interframe space* (SIFS) and transmits the ACK. The SIFS value is smaller than the DIFS value. All IFS values depend on the physical layer alternative. Thus, any other MS that senses the channel as idle after the original frame was transmitted will still be waiting, and ACK frames have priority over their transmissions. To maintain fairness and avoid collisions, the MS that senses the medium as free for a time DIFS and transmits a frame will have to enter the backoff process if it wants to transmit another frame immediately. The exception is when it is transmitting one frame in many fragments. In such a case, the MS can indicate the number of fragments in the first frame to be transmitted and occupy the channel until the frame is completely transmitted.

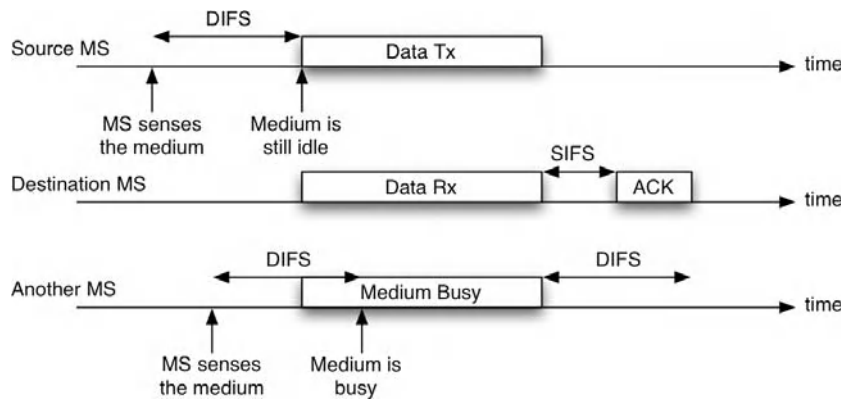

Figure 3: Basic medium access in IEEE 802.11

Figure 4: Backoff process in IEEE 802.11

The backoff process works as follows. Once an MS enters the backoff process, it picks a value called the *backoff interval* (BI) that is a random value uniformly distributed between zero and a number called the *contention window* (CW). The MS will then monitor the medium. When the medium is free for at least a time DIFS, the MS will start counting down from the BI value as long as the medium is free. The counter is decremented every so often (called a *slot*). If the medium is sensed as occupied before the counter goes down to zero, the MS will freeze the counter and continue to monitor the medium. As soon the counter becomes zero, the MS can transmit its frame. This process is shown in Figure 4.

The IEEE 802.11 MAC supports *binary exponential backoff* like IEEE 802.3. Initially, the CW is maintained at a value called CW_{min} , which is typically $2^5 - 1 = 31$ slots. So the BI will be uniformly distributed between 0 and 31 slots. The slot time varies, depending on the physical layer alternative. For example, it is 20 μs in the IEEE 802.11b standard and 9 μs in the 802.11a standard. If a packet is not successfully transmitted (this could be the result of collisions or a channel error), the value of CW is essentially doubled. The MS will now pick a BI value that is uniformly distributed between 0 and $2^6 - 1 = 63$ slots. This process can be continued till CW reaches a value that is CW_{max} (usually 1023 slots). The rationale behind this approach is as follows. If there are many MSs contending for the medium, then it is likely that one or more may pick the same BI value. Their transmissions will then collide. By increasing the value of CW, it is likely that this probability will go down, thereby reducing collisions.

Frames may be lost because of channel errors or collisions. A positive ACK from the destination is necessary to ensure that the frame has been successfully received. In IEEE 802.11, each MS maintains retry counters that are incremented if no ACKs are received. After a retry threshold is reached, the frame is discarded as being undeliverable.

The Hidden Terminal Problem and Optional Mechanism

In wireless networks that use carrier sensing, there is a unique problem called the *hidden terminal problem*. Suppose all MSs are identical and have a transmission and reception range of R as shown in Figure 5.

The transmission from MS-A can be heard by MS-C but not by MS-B. So when MS-A is transmitting a frame to MS-C, MS-B will not sense the channel as busy: MS-A is *hidden* from MS-B. If both MS-A and MS-B transmit frames to MS-C at the same time, then the frames will collide. This is the hidden terminal problem. There is a dual problem called the *exposed terminal problem*. In this case, MS-A is transmitting a frame to MS-D. This transmission is heard by MS-C, which then backs off. However, MS-C could have transmitted a frame to MS-B, and the two transmissions would not interfere or collide. In this case, MS-A is called an *exposed terminal*. Both hidden and exposed terminals cause a loss of throughput.

To reduce the possibility of collisions because of the hidden terminal problem, the IEEE 802.11 MAC has an optional mechanism at the MAC layer as shown

Figure 5: Illustrating the hidden and exposed terminal problems

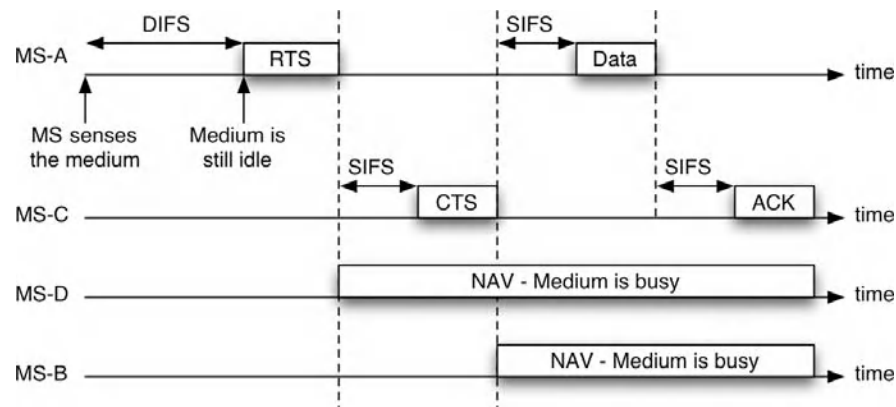

Figure 6: Operation of the RTS-CTS mechanism

in Figure 6. Suppose MS-A wants to transmit a frame to MS-C. It will first transmit a short frame called the *request-to-send* (RTS) frame. The RTS frame is heard in the transmission range of MS-A and includes MS-C and MS-D, but not MS-B. Both MS-C and MS-D are alerted to the fact that MS-A intends to transmit a frame and they will not attempt to simultaneously use the medium. This is achieved by the virtual carrier sensing process that sets the NAV to a value equal to the time it will take to successfully complete the exchange of frames. In response to the RTS frame, MS-C will send a *clear-to-send* (CTS) frame that will be heard by all MSs in its transmission range. This includes MS-B and MS-A but not MS-D. The CTS frame lets MS-A know that MS-C is ready to receive the data frame. It also alerts MS-B to the fact that there will be a transmission from some MS to MS-C. Consequently MS-B will defer any frames that it wishes to transmit in anticipation of the completion of the communication to MS-C. This way, even though MS-B is outside the transmission range of MS-A, the CTS message can be used to

extend the carrier sensing range, thereby reducing the hidden terminal problem. Of course, it is quite possible that the RTS frame itself collided with a transmission from MS-B. In such a case, both MS-A and MS-B will have to enter the backoff process and retransmit their frames.

The RTS-CTS mechanism can be controlled in IEEE 802.11 by using an RTS threshold. All unicast and management frames larger than this threshold will always be transmitted using RTS-CTS. By setting this value to 0 bytes, all frames will use RTS-CTS. The default value is 2347 bytes, which disables RTS-CTS for all packets. When RTS-CTS signals are used, the CTS frame is transmitted by the destination MS after waiting simply for a time equal to SIFS. This way, the CTS frame has priority compared to all other transmissions that have to wait for at least a time DIFS and perhaps an additional waiting time in backoff. Using the RTS-CTS signals reduces the throughput of a WLAN, but it may be essential to use this in dense environments.

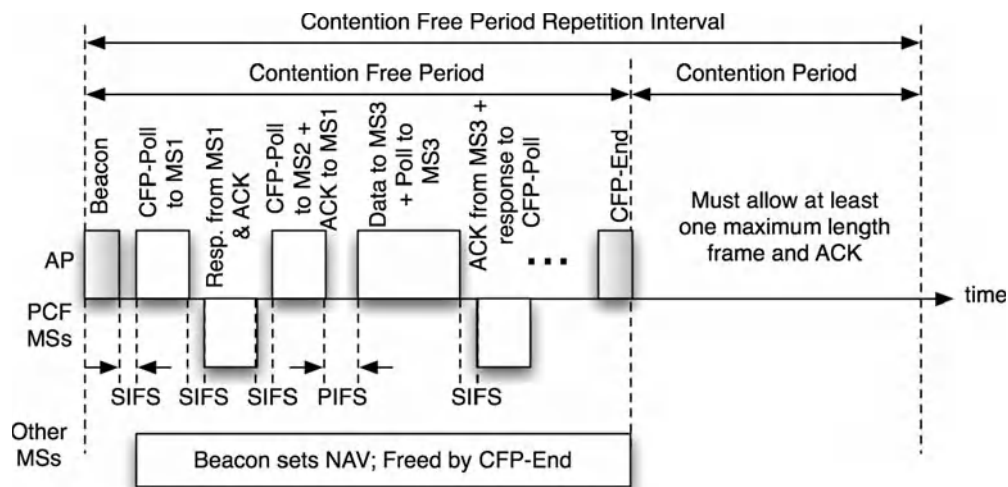

Figure 7: Operation of the PCF

The Point Coordination Function

One consequence of using CSMA/CA as described above with DCF is that it is impossible to have any bounds on the delay or jitter suffered by frames. Depending on the traffic load and the BI values that are picked, a frame may be transmitted instantaneously or it may have to be buffered until the medium becomes free. For real-time applications such as voice or multimedia, this can result in performance degradation, especially when strict delay bounds are necessary. To provide some bounds on the delay, an optional MAC mechanism—the point coordination function—is part of the IEEE 802.11 standard (Crow et al. 1997). PCF provides contention-free access to frames using a polling mechanism described below.

The process starts when the AP captures the medium by sending a beacon frame after it is idle for a time called the *PCF interframe space* (PIFS). The PIFS is smaller than the DIFS and larger than the SIFS. In the beacon frame, the AP, also called the *point coordinator*, announces a *contention-free period* (CFP) in which the usual DCF operation will be preempted. All MSs that use only DCF will set a NAV to indicate that the medium will be busy for the duration of the CFP. The AP maintains a list of MSs that need to be polled during the CFP. MSs get onto the polling list when they first associate with the AP using the association request. The AP then polls each MS on the list for data. The polls are sent after a time

SIFS, and the ACKS to the poll and any associated data will be transmitted by the corresponding MS also after a time SIFS. If there is no response from a MS to a poll, the AP waits for a time PIFS before it sends the next poll frame or data. The AP can also send management frames whenever it chooses within the CFP. An example of PCF operations is shown in Figure 7.

The AP indicates the culmination of the CFP via a message called *CFP-End*. This is a broadcast frame to all MSs and frees the NAV in MSs that are only DCF-based. Following the CFP, a contention period starts. In this period, it must be possible for a MS to transmit at least one maximum length frame using DCF and to receive an ACK. The CFP can be resumed after completion of the contention period. The PCF mechanism is optional in IEEE 802.11. Most commercial systems deployed today do not support PCF, and real-time services do not have good support in WLANs today. Note that polling has a lot of overhead, especially if MSs do not have frames to send when they are polled.

MAC Frame Formats

Although this chapter will not define all of the different frame formats of an IEEE 802.11 MAC frame and discuss the fields in great detail, it will consider examples to illustrate the MAC frame formats. Figure 8 shows the general format of a MAC frame. The most significant bit is last (right-most), and the bits are transmitted from left

Figure 8: General format of a MAC frame

Figure 9: RTS and CTS frame formats

Time Stamp 8 bytes	Beacon Interval 2 bytes	Capab. Info. 2 bytes	SSID Variable	FH Parameter Set 7 bytes	DS Param Set 2 bytes	CF Parameter Set 8 bytes	IBSS Parameter Set 4 bytes	TIM Var.
-----------------------	----------------------------	-------------------------	------------------	-----------------------------	-------------------------	-----------------------------	-------------------------------	-------------

Figure 10: Frame body of the beacon frame

to right. The frame control field has two bytes and comprises many fields. It carries information such as:

- the protocol version;
- the type of frame, including
 - management (probe request, association, authentication, and so on),
 - control (RTS, CTS, and so on, or data),
 - pure data (CFP poll and data, and null);
- the number of retries; and
- whether the frame is encrypted (discussed later).

The duration field is important to set the NAV during virtual carrier sensing.

There can be as many as four address fields in the frame (Gast 2002). The addresses can be different, depending on the type of frame. Common addresses used are the source and destination addresses, the receiver address if the destination is different from the receiver (e.g., the receiver is the AP, but the destination is a wired node on the LAN segment), the transmitter address (once again if the transmitter is different from the source, it is the AP), and the BSSID. The sequence control field is used in case there is fragmentation of frames. The frame body carries the payload from upper layers and the frame check sequence is a 32-bit cyclic redundancy check used to verify the integrity of the frame at the receiver. The frame format in Figure 8 is used in an infrastructure topology. In an IBSS, only three address fields are used.

The RTS and CTS frames are short frames: twenty and fourteen bytes, respectively (see Figure 9). The ACK frames are similar to the CTS frame.

Figure 10 illustrates the frame body of the beacon frame. The time stamp allows MSs to synchronize to a BSS. The beacon interval says how often the beacon can be expected to be heard. It is typically 100 milliseconds but could be changed by an administrator. The capability information (two bytes) provides information about the topology (whether infrastructure or ad hoc), whether encryption is mandatory, and whether additional features

are supported. One such feature is *channel agility* by which the AP hops to different channels after a predetermined amount of time.

We have not discussed PHY layer alternatives yet. The parameter sets in the beacon provide information about the PHY layer parameters that are necessary to join the network. For instance, if frequency hopping is used, the FH parameter set will specify the hopping pattern. The TIM field is used to support MSs that may be sleeping as described earlier.

THE IEEE 802.11 PHYSICAL LAYER ALTERNATIVES

The IEEE 802.11 standards body has standardized several different PHY layer alternatives. When it was first standardized in 1997, there were three PHY layer options. We will call these options as the “base” IEEE 802.11 PHY layer alternatives. The IEEE 802.11b supports as much as 11 Mbps in the 2.4-GHz ISM bands, the IEEE 802.11g standard supports as much as 54 Mbps in the 2.4-GHz ISM bands, and the IEEE 802.11a standard supports as much as 54 Mbps in the 5-GHz UNII bands. Before we discuss these alternatives, let us look at the PHY layer in IEEE 802.11.

The PHY layer in IEEE 802.11 is broken into two sublayers: the *physical layer convergence protocol* (PLCP) and the *physical medium dependent* (PMD) layers. The PLCP includes a function that adapts the underlying medium dependent capabilities to the MAC-level requirements. The PLCP would, for instance, add additional fields to the frame to enable synchronization at the physical layer. The PMD actually determines how information bits are transmitted over the medium.

The Base IEEE 802.11 Standard

The base IEEE 802.11 standard specifies three different PHY layer alternatives. Two of these use RF transmissions in the 2.4 GHz ISM bands and one uses IR.

The FH Option

The first option for transmission in the 2.4-GHz ISM bands makes use of *frequency hopping spread spectrum* (FHSS) (Pahlavan and Krishnamurthy 2002). The entire band is divided into 1-MHz wide channels, and the specification makes it important to confine 99 percent of the energy to one such channel during transmission to reduce interference to the other channels. These restrictions are also due to the rules imposed by the Federal Communications Commission (FCC) in the United States. The standard specifies ninety-five such 1-MHz wide channels, and they are numbered accordingly. In the United States, only seventy-nine of these channels are allowed. Devices that use the FH option hop between these channels when transmitting frames. The dwell time in each channel is approximately 0.4 s. The hop sequences (the channel hopping pattern) depends on mathematical functions. An example hopping pattern is {3, 26, 65, 11, 46, 19, 74, . . . }. In the United States, each set of hopping patterns can have twenty-six different channels at most. This means that it is possible to create three orthogonal hopping sets (because there are seventy-nine channels in the United States). If three APs use these three orthogonal hopping sets, then there will be no interference between these networks. The modulation scheme used with FHSS is called *Gaussian frequency shift keying* (GFSK). This modulation scheme makes use of the frequency information to encode data. It is possible to use either (1) two frequencies within the channel or (2) four frequencies within the channel. In the former case, the data rate will be 1 Mbps; in the latter case, the data rate will be 2 Mbps. The advantage of the FHSS system is that the receivers are less complex to implement. The PLCP for the FHSS PMD introduces an eighty-bit field for synchronization, a frame delimiter, and fields to indicate the data rate. Depending on this field, the data rate can be modified in steps of 500 kbps from 1 Mbps to 4.5 Mbps. However, the standard only supports 1 and 2 Mbps. The values of SIFS and the slot for backoff in this option are 28 μ s and 50 μ s, respectively.

The DS Option

The direct sequence spread spectrum modulation technique has been the most popular commercial implementation of IEEE 802.11. DSSS has inherent advantages in multipath channels and can increase the coverage of an AP for this reason (Tuch 1991). We will briefly discuss the features of this PMD layer.

In a DSSS system, the data stream is “chipped” into several narrower pulses (chips), thereby increasing the occupied spectrum of the transmitted signal. One common way of doing this is to multiply the data stream (typically a series of positive and negative rectangular pulses) by a spreading signal (typically another series of positive and negative rectangular pulses but with much narrower pulses than the data stream). Although the data stream is random and depends on what needs to be transmitted, the spreading signal is deterministic. Figure 11a shows an example where the data stream $d(t)$ is multiplied by a spreading signal $a(t)$ to produce a signal $s(t)$ that is then modulated over an RF carrier. In this figure, eleven narrow pulses are contained within one broad data pulse. The pulses could have a positive (+) or negative (–) amplitude. This results in the bandwidth expanding by a factor of 11; this is also called the *processing gain*. A specific pattern of pulses in the spreading signal is used. The pattern used in the IEEE 802.11 standard is a Barker sequence. The interesting property of the Barker sequence is that its autocorrelation has a sharp peak and narrow side lobes as shown in Figure 11b. Because of this property, it is possible for a receiver to reject interference from multipath signals and recover information robustly in a harsh wireless environment. The Barker sequence with *differential binary phase shift keying* (DBPSK) is used for data rates of 1 Mbps; the Barker sequence with *differential quadrature phase shift keying* (DQPSK) is used for data rates of 2 Mbps. In either case, the chip rate is 11 Mcps (mega chips per second).

Unlike FHSS, a signal carrying 2 Mbps now occupies a bandwidth that is as large as 25 MHz. In the IEEE 802.11 standard, fourteen channels are specified for the

Figure 11: (a) Direct sequence spread spectrum and (b) autocorrelation of the Barker pulse

Figure 12: Channelization for IEEE 802.11 DS option

DSSS PMD. Channel 1 is at 2.412 GHz, channel 2 at 2.417 GHz, and so on. Only the first eleven channels are available for use in the United States. Figure 12 shows the channelization in the United States. Because each channel occupies roughly 25 MHz bandwidth and the channel separation is only 5 MHz, there is significant overlap between channels. If two WLANs in the same vicinity were to use adjacent channels, there would be severe interference and throughput degradation. There are three orthogonal channels—channels 1, 6, and 11—in the United States that can be deployed without interference.

The PLCP sublayer once again introduces fields for synchronization (128 bits), frame delimiting, and error checking. The PLCP header and preamble are always transmitted at 1 Mbps using DBPSK. The rest of the packet is transmitted using either DBPSK or DQPSK, depending on the data rate. The values of SIFS and the slot for backoff in this option are 10 μ s and 20 μ s, respectively.

The IR Option

The third option in IEEE 802.11 is to use infrared for transmission (Valadas et al. 1998). The spectrum occupied by the IR transmission is at wavelengths between 850 nm and 950 nm. The technique used for transmission is diffused infrared—that is, communications is omnidirectional. The range specified is approximately 20 m, but the transmissions cannot penetrate physical obstacles. The modulation scheme used is PPM. A data rate of 1 Mbps is supported using 16-PPM, and a data rate of 2 Mbps is supported using 4-PPM. This is in comparison with the infrared data association (IrDA) standard, which primarily allows communications at a few hundred kbps to a few Mbps between two devices (such as a laptop and a personal digital assistant) that are within a few feet of one another.

The IEEE 802.11b and g Standards

The DS option for IEEE 802.11, although successful, consumed a lot of bandwidth for the given data rate. The chip rate is 11 Mcps, but the maximum data rate is 2 Mbps. In other words, one Barker sequence of eleven chips, transmitted every microsecond, can at most carry two bits of information. To increase the data rate, the IEEE 802.11b standard adopted a slightly different method. Instead of transmitting one eleven-chip sequence every microsecond, with IEEE 802.11b the device transmits

Table 2: Mapping for CCK

Dibit	Phase Parameter	Dibit (d_{i+1}, d_i)	Phase
(d1, d0)	φ_1	(0,0)	0
(d3, d2)	φ_2	(0,1)	π
(d5, d4)	φ_3	(1,0)	$\pi/2$
(d7, d6)	φ_4	(1,1)	$-\pi/2$

one eight-chip code word every 0.727 microseconds. Each eight-chip code word can carry as many as eight bits of information for a maximum data rate of $8/(0.727 \times 10^{-6}) = 11$ Mbps. If the code word carries only four bits of information, the data rate will be 5.5 Mbps. The code words are derived from complementary code keying (Halford et al. 1999).

CCK works as follows for the case when eight bits are mapped into an eight-chip code word. The incoming data stream is broken into units of eight bits. Suppose the least significant bit is labeled d0, and the most significant bit is labeled d7. Then four phases are defined to correspond to the four possible values of a pair of bits as shown in the first two columns of Table 2. Depending on what the bits are, the phases then take on a value as shown in the third and fourth columns in Table 2. For example, if d5 = 0 and d4 = 1, then the phase $\varphi_3 = \pi$. Once the phases are determined, the eight-chip code word is given by the vector

$$\mathbf{C} = \left\{ e^{j(\varphi_1 + \varphi_2 + \varphi_3 + \varphi_4)}, e^{j(\varphi_1 + \varphi_3 + \varphi_4)}, e^{j(\varphi_1 + \varphi_2 + \varphi_4)}, -e^{j(\varphi_1 + \varphi_4)}, \right. \\ \left. e^{j(\varphi_1 + \varphi_2 + \varphi_3)}, e^{j(\varphi_1 + \varphi_3)}, -e^{j(\varphi_1 + \varphi_2)}, e^{j(\varphi_1)} \right\}$$

This vector has elements that belong to the set $\{+1, -1, +j, -j\}$, where j is the square root of -1 . These four elements can be mapped in RF to the phase of the carrier, and the receiver can decode this phase information to recover the data bits (Pahlavan and Krishnamurthy 2002). CCK can be thought of as either a modulation scheme or a coding scheme.

The advantage of CCK is that it maintains the channelization of IEEE 802.11 while increasing the data rate by a factor of 5. CCK is also fairly robust to the degradations caused by multipath in the wireless environment. The values of SIFS and the slot for backoff in this option

are 10 μ s and 20 μ s, respectively. IEEE 802.11b also has an optional modulation method called *packet binary convolutional coding* (PBCC) that is not widely implemented. The advantage of PBCC over CCK is the use of powerful convolutional coding for forward error correction.

The IEEE 802.11g standard (Vassiss et al. 2005) maintains backward compatibility with IEEE 802.11b and IEEE 802.11 DS options by adopting minimal PHY layer frame changes and by including some mandatory and optional physical layer components. In the PLCP layer, 802.11g allows for the use of short preambles to reduce packet overhead. The four physical layers specified in this standard are prefixed by the term ERP, which stands for *extended rate physical*. The standard specifies orthogonal frequency division multiplexing and CCK as the mandatory modulation schemes with a data rate of 24 Mbps as the maximum mandatory data rate. With OFDM, IEEE 802.11g also provides for optional higher data rates of 36, 48, and 54 Mbps. OFDM is the same modulation scheme that is used in IEEE 802.11a and we discuss it below. PBCC is an optional modulation scheme in 802.11g that allows for raw data rates of 22 and 33 Mbps. We discuss OFDM in the context of 802.11a below, but the discussion could also apply to 802.11g with some modifications.

The IEEE 802.11a Standard

One primary problem for huge data rates in wireless channels is the coherence bandwidth of the wireless channel caused by multipath dispersion. The coherence bandwidth limits the maximum data rate of the channel to that which can be supported within this bandwidth (for example, if the coherence bandwidth is B Hz and the channel bandwidth is $W \gg B$ Hz, a transmission bandwidth of W Hz will result in irrecoverable errors unless equalization or spread spectrum is used). To overcome this limitation, we can send data in several subchannels, each on the order of the coherence bandwidth or less,

so that many of them will get through correctly. Using several subchannels and reducing the data rate on each channel increases the symbol duration in each channel. If the symbol duration in each channel is larger than the multipath dispersion, errors will be smaller and it will be possible to support larger data rates. This principle can be exploited while maintaining bandwidth efficiency using a fairly old technique: OFDM. OFDM has been used in digital subscriber lines as well to overcome the variations in attenuation with frequency over copper lines. OFDM enables spacing carriers (subchannels) as closely as possible, and implementing the system completely in digital eliminates analog components to the extent possible. OFDM (Kapp 2002) is used as the physical layer in IEEE 802.11a, HIPERLAN/2, and IEEE 802.11g.

IEEE 802.11a specifies eight 20-MHz channels (Van Nee et al. 1999). As shown in Figure 13, several subchannels are created in OFDM using orthogonal carriers in each channel. Fifty-two subchannels are specified for each channel with a bandwidth of approximately 300 kHz each. Forty-eight subchannels are used for data transmission, and four are used as pilot channels for synchronization. One OFDM symbol (consisting of the sum of the symbols on all carriers) lasts for 4 microseconds and carries anywhere between 48 and 288 coded bits. For example, at 54 Mbps, the OFDM symbol has 216 data symbols. With a code rate of 3/4, the number of coded bits/symbol will be $4 \times 216/3 = 288$. This is possible by using different modulation schemes ranging from BPSK, which has one bit per subchannel, to more complex modulation schemes such as *quadrature amplitude modulation* (QAM) that support multiple bits per subchannel. Error control coding also plays an important role in determining the data rate. Table 3 summarizes some features of the different supported data rates.

The PLCP in the case of 802.11a is a bit different in that there is no synchronization field. A rate field with four bits indicates the data rate that is being transmitted.

Figure 13: Orthogonal carriers in OFDM

Table 3: Data Rates and Associated Parameters in IEEE 802.11a

Data Rate (Mbps)	Modulation	Code Rate	Data Bits/Symbol	Coded Bits/ Subchannel	PLCP Rate Field
6	BPSK	1/2	24	1	1101
9	BPSK	3/4	36	1	1111
12	QPSK	1/2	48	2	0101
18	QPSK	3/4	72	2	0111
24	16-QAM	1/2	96	4	1001
36	16-QAM	3/4	144	4	1011
48	64-QAM	2/3	192	6	0001
54	64-QAM	3/4	216	6	0011

This field is shown in Table 3 for different data rates. The preamble and header are always modulated using BPSK (lower data rates). The values of SIFS and the slot for backoff in this option are 16 μ s and 9 μ s, respectively.

The IEEE 802.11n Standard

The current MAC and PHY layers of the IEEE 802.11 standard constrain the raw data rate to 54 Mbps and the throughput to a fraction of that depending on traffic load, channel conditions, and so on. A new task group is looking at an IEEE 802.11n standard that will look at both MAC and PHY enhancements that improve the throughput to more than 100 Mbps (as high as 600 Mbps). Note that this is not the raw data rate on the air, but the actual throughput of the network. Some of the ideas being floated to improve throughput are to use directional antennae, MIMO with OFDM, and throughput enhancements at the MAC layer. MIMO enables the spectral efficiency of links to go well above the 1 bps/Hz that is usually the order in traditional systems. This increase in spectral efficiency is possible through the use of such space-time techniques (Haykin and Moher 2005) as space-time coding, beam forming, and spatial multiplexing. These techniques either increase the reliability of the link through diversity or increase capacity by canceling interference from the simultaneous transmission of multiple data streams from multiple antennae.

The primary MAC enhancement to improve throughput in 802.11n is the use of frame aggregation to reduce

overhead (Xiao 2005). At extremely high data rates, the overhead of waiting times, backoff, and frame headers can reduce throughput significantly. One method of reducing this overhead is to aggregate frames either at the MAC layer or the PHY layer. Similarly, acknowledgments can also be delayed and aggregated. Frame aggregation can be used for single destinations and multiple destinations, and it can use multiple rates for multiple destinations.

For some time, there were two competing proposals in Task Group N for the PHY and MAC layers—worldwide spectrum efficiency (WWiSE) and TGnSync—with many vendors in each group. Both proposals used MIMO at the physical layer. Products that conform to parts of these proposals were also available in the market. Neither proposal was successful in obtaining 75 percent of the vote. In January 2006, these two proposals merged with a third proposal that has been now submitted for approval. The industry consortium driving this new proposal is called the Enhanced Wireless Consortium. The organization's stated goal is to "help accelerate the IEEE 802.11n development process and promote a technology specification for interoperability of next-generation WLAN products."

Summary of PHY Layer Alternatives

Table 4 summarizes the different PHY layer alternatives in IEEE 802.11.

Table 4: Summary of PHY Alternatives in IEEE 802.11

Standard	Spectrum: United States (GHz)	Data Rates	Modulation Scheme
Base IEEE 802.11	2.402–2.479	1, 2 Mbps	GFSK, FHSS
	2.402–2.479	1, 2 Mbps	B/QPSK, DSSS
	850–950 nm	1, 2 Mbps	PPM, IR
802.11a	5.15–5.35, 5.725–5.825	6–54 Mbps	OFDM
802.11b	2.402–2.479	1, 2, 5.5, 11 Mbps	CCK
802.11g	2.402–2.479	1–54 Mbps	OFDM, CCK
802.11n	2.4 and 5 GHz	>100 Mbps	MIMO/OFDM

SECURITY ISSUES AND IMPLEMENTATION IN IEEE 802.11

Security in wireless networks is an important problem, especially because it is extremely difficult to contain radio signals within a protected perimeter (Edney and Arbaugh 2004). Anyone can listen to radio signals, and anyone can also potentially inject signals into the network. Typically, in any wireless or wired network, it is common to deploy security features or services such as confidentiality, entity authentication, data authentication, and integrity and so on to protect against security threats (Stinson 2002). The IEEE 802.11 standard has some mechanisms to provide confidentiality, integrity, and authentication at the link level. All data that leave the 802.11 link will not be protected. For instance, an MS communicating with an AP can have all its IEEE 802.11 frames that are on the air protected. Once the AP receives the frame, all protection is removed before it is transmitted on the distribution system. So additional security at the higher layers (such as IPSec or the *secure sockets layer*, SSL) may be required for some applications if the payload needs to be secure.

The original mechanism for providing confidentiality and authentication in IEEE 802.11 is called *wired equivalent privacy* (WEP) (Gast 2002). Over the last few years, several techniques for compromising WEP have been published in the literature. Tools such as AirCrack, Kismet, and WEPcrack are freely available and can be used to extract the secret key used in WEP encryption. WEP makes use of the RC4 stream cipher with forty-bit keys (although there are options to use 128-bit keys in most commercial products today). Both the implementation of WEP and the RC4 algorithm itself have vulnerabilities that have rendered WEP insecure for today's applications. WEP was initially proposed in the standard as a self-synchronizing, exportable, and efficient option. Although it does satisfy these three properties, its security has left much to be desired.

In what follows we discuss the original implementation of security in IEEE 802.11 and discuss enhancements that have been recently proposed.

Entity Authentication in IEEE 802.11

The mandatory entity authentication mechanism in IEEE 802.11 is called *open system authentication*. In this case, there is no real authentication. If one IEEE 802.11 device sends a frame to another, it is implicitly accepted. For example, an MS may simply send a frame to the AP choosing "open system" as the authentication algorithm (authentication algorithm = 0). The AP will simply accept it (if open system access is allowed) and send a response. From this transaction, the AP will obtain the MAC address of the MS for communication purposes.

A better authentication procedure is called *shared-key authentication*, in which WEP is implemented (Gast 2002). If the network is using WEP, shared-key authentication is mandatory. The assumption is that all devices in the network share a secret key. An MS will send a frame for authentication with sequence number 0, the authentication algorithm set to 1 (to indicate shared-key authentication). The AP will then send a challenge message (128 bits) in

clear text to the MS along with its response. The MS will respond with an encrypted version of the challenge text. If the AP is able to verify the integrity of the reply, the MS is authenticated and it has the shared WEP key configured in it. Sometimes an MS will authenticate itself with several APs before associating itself with one of them. This process is called *preauthentication*. This authentication scheme is still not especially secure, however, and it also creates weaknesses in the protocol because of the way in which it is employed with a stream cipher.

Several commercial products also implement address filtering in which only certain MAC addresses are allowed access to the network. This is not part of the standard, and it is also possible for malicious users to spoof MAC addresses easily. However, address filtering is an additional security measure that is available for IEEE 802.11 networks.

Confidentiality and Integrity in IEEE 802.11

Confidentiality is simply provided in IEEE 802.11 by encrypting all packets using the RC4 stream cipher. Stream ciphers operate as follows. Using a secret key, a pseudo-random sequence of bits (the *key stream*) is generated. If this sequence has an especially long period and the algorithm is strong, it will be computationally impossible for someone to generate the sequence without knowing the secret key. The pseudo-random sequence thus generated will be XOR-ed with the MAC frame to make the contents of the frame secure from interception. RC4 is one algorithm to generate the pseudo-random key stream. This algorithm makes use of a secret key; in the case of WEP, it uses an *initialization vector* (IV) that is 24 bits long. Because the key is constant for all transactions, the same pseudo-random key stream is generated if the IV is not changed. An attacker could capture two streams of encrypted frames, XOR them together, eliminate the key stream, and then have an XOR of two data frames. If by some chance the attacker knows the contents of one data frame, he can get the other as well. Because the IV is only 24 bits long, it is still possible for an attacker to break the encryption scheme. One well publicized attack is the Fluhrer, Mantin, Shamir attack on RC4. In addition, there are several weak keys that could make the encryption scheme easier to break. It is also possible for an attacker to replay packets, depending on the sequence numbers that are being used. To ensure that an attacker has not modified a message, the WEP protocol uses the built-in *cyclic redundancy check* (CRC) to verify the integrity of the message. Checking the integrity of the message using the CRC has vulnerabilities that have been publicized in recent years.

Key Distribution in IEEE 802.11

The IEEE 802.11 standard does not specify how the shared keys must be distributed to devices (AP and MSs). It is usually a manual installation of keys by which a user will type the key in the device driver software. Unfortunately, this process is not scalable and has several human vulnerabilities. Users may write down the key on a piece of paper when they buy a new device and lose

this paper. Some vendors have automated methods of key distribution. Cisco's light extensible authentication protocol makes use of the challenge-response mechanism to generate a key at the AP and an identical matching key locally in the MS that could then be used in a successful encrypted communication.

Security Features in 802.11i

Task Group I of the IEEE 802.11 working group has prepared an enhanced security framework for IEEE 802.11 called 802.11i that was approved as a standard in June 2004. Several vendors have already implemented elements of this standard. This framework includes what is called a *robust security network* (RSN) that is similar to WEP, but has several new capabilities in devices (Edney and Arbaugh 2004). It is possible for both WEP and RSN devices to coexist in a transitional security network.

A consortium of major WLAN manufacturers called the Wi-Fi Alliance considered options to improve security in legacy devices while 802.11i was being standardized. The proposal from this alliance is called *Wi-Fi protected access* (WPA) that introduces enhancements to WEP called *temporal key integrity protocol* (TKIP). In this protocol, RC4 is still used as the encryption algorithm. However, this protocol adds features that overcome WEP's weaknesses. A message integrity code is used instead of the CRC check. It changes the way in which IVs are generated. It changes the encryption key for every frame, increases the size of the IV, and also adds a mechanism to manage keys.

In 802.11i, RC4 is replaced by the *advanced encryption standard* (AES). In particular, the key stream and message integrity check will be generated by a *counter mode cipher block chaining MAC protocol* (CCMP). AES is a block cipher—that is, it operates on fixed blocks of data unlike a stream cipher, which generates a key stream. However, any block cipher can operate in many different standardized modes, and *cipher block chaining* (CBC) is one such mode of operation. The counter mode is another standardized mode of operation. It is expected that the counter mode will be used to generate the key stream, and the CBC will be used to generate the message integrity check. Both of these modes have been used in other systems with good security.

Both TKIP and AES-CCMP provide confidentiality and message integrity. To perform entity authentication, the IEEE 802.11 system has to still rely on challenge-response protocols. Over the years, there have been several protocols developed for dialup entity authentication and for port security in wired LANs. These include 802.1X, the *extensible authentication protocol* (EAP) and *remote authentication dial-in user service* (RADIUS). Note that all of these protocols are not equivalent. For instance, both 802.1X and RADIUS could use EAP for entity authentication and key distribution. EAP itself would use some challenge-response protocol such as challenge handshake authentication protocol (CHAP) or SSL to authenticate the devices. Both WPA and RSN mandate 802.1X and EAP as part of the access control mechanism for 802.11 networks. Note that access control is increasingly becoming an important problem with the emergence of hot spot networks in airports, cafes, and so on.

RECENT ACTIVITIES

There are some other amendments to the 802.11 standard that have been approved recently. They do not directly change the protocol on the air in the United States, but they do provide extensions to the way 802.11 systems may operate. One important issue in wireless networks is roaming between different points of access to the wired network. This is possible only if equipment from different vendors supports the same set of protocols and is interoperable. Previously, there existed a Task Group F that had proposed an *interaccess point protocol* (IAPP) to achieve multivendor interoperability. For example, when an MS moves from one AP to another and sends a reassociation request, the new AP must be able to converse with the old AP over the distribution system to inform it of the handoff and to free the resources in the old AP. This is achieved using the IAPP now standardized as 802.11f in July 2003. The 802.11f standard specifies the information and format of the information to be exchanged between access points and includes the recommended practice for multivendor access point interoperability via the IAPP across distribution systems. The competing standard for wireless LANs in Europe is the HIPERLAN/2 standard that is specified for the UNII bands. HIPERLAN/2 uses the same physical layer as IEEE 802.11a although it accommodates a few different data rates. In this standard, mechanisms are suggested for power measurement and control and radio resources management. Previously, too, there existed a Task Group H that was enhancing the current 802.11 MAC and 802.11a PHY with network management and control extensions for spectrum and transmit power management in the UNII bands with the possibility of dynamic channel selection capabilities. In this case, APs would be able to dynamically select channels based on information they can obtain about neighboring APs that may be transmitting on the same channel. This way, a laborious network planning process could be simplified. The 802.11h standard completed in October 2003 ensures that *transmit power control* and *dynamic frequency selection* satisfy the regulatory aspects in Europe.

Outside of the standards that have been specified already, there are several ongoing activities in the IEEE 802.11 working group. Several task groups are engaged in enhancing aspects of the IEEE 802.11 standard (see Table 5 for a summary). Some of these follows.

Task Group E: The 802.11 DCF considers all traffic to be the same and provides only a best effort service. This task group has developed enhancements to the MAC layer so as to provide some mechanisms for supporting *quality of service* (QoS) in wireless LANs for real-time applications such as audio, video, and media stream distribution. One technique that is being actively considered is to have different inter-frame space and contention window values for different classes of traffic. For example, a traffic class with higher priority would have a smaller IFS and CW range so that it waits for a smaller time compared to a traffic class with lower priority. This way, time-sensitive traffic could get access to the channel earlier. Different traffic classes have different queues in the MS,

Table 5: Summary of Task Groups and Status

Group	Group Activities	Status as of September 2006
A	5-GHz operation (high data rate extension based on OFDM)	Completed
B	2.4-GHz operation (high data rate extension as high as 11 Mbps)	Completed
E	QoS enhancements to the MAC layer	Completed (November 2005)
F	Inter Access Point Protocol	Completed (July 2003)
G	2.4-GHz operation (high data rate extension as high as 54 Mbps)	Completed
H	Spectrum and transmit power management in Europe	Completed (October 2003)
I	Security enhancements to 802.11	Completed (June 2004)
J	Operation in 4.9-GHz to 5-GHz bands in Japan	In progress
K	Radio resource management	In progress
N	High throughputs greater than 100 Mbps	Draft 1.02 in July 2006
P	Wireless access for the vehicular environment	In progress, voting on draft
R	Fast roaming between access points	In progress
S	Mesh networking of access points	In progress (started in 2004)
Y	Operation in the 3.5-GHz bands	In progress

enabling them to be treated differently. This technique is similar to service differentiation in wired networks (Pattara-atikom, Krishnamurthy, and Banerjee 2003). The MAC protocol is called *enhanced distributed channel access*. The ability to differentiate between traffic classes has become more important for *voice over IP* (VoIP) applications. The 802.11e standard was approved in November 2005.

Task Group J: This task group is considering enhancements to the current standard to provide operations in the frequency band between 4.9 GHz and 5 GHz for use in Japan. The reason for this task group is to make changes in the 802.11 standard to accommodate the regulatory demands in this spectrum in Japan. There will be expected changes to both the MAC and PHY layers to meet these regulations.

Task Group K: This task group is looking at enhanced radio resource management outside the purview of 802.11h. The primary goal of this group is to provide mechanisms to higher layers that enable radio and network measurements as necessary. Once power measurements and reporting are possible in a standardized manner, they can be exploited to make better use of the spectrum, reduce interference, and so on.

Task Group P: Future road transportation is expected to evolve into an *intelligent transportation system* (ITS). The goal of Task Group P (called *wireless access for the vehicular environment*, or WAVE) is to define enhancements to 802.11 that may be required to support ITS applications. Such definitions will include

data exchange between high-speed vehicles and between these vehicles and the roadside infrastructure in the licensed ITS band (5.9 GHz).

Task Group R: In an authenticated system using 802.11i or even WEP, there is a substantial delay because of the reassociation and reauthentication procedures when an 802.11 device hands off from one BSS to another within an ESS. Such delays can be as high as 15 s and are unacceptable for real-time traffic. As VoIP becomes more important and its use over wireless LANs increases, these delays must be reduced to acceptable levels without compromising security. Such enhancements to the current 802.11 standard to provide fast handoffs between different BSSs is the responsibility of Task Group R.

Task Group S: As previously discussed, the idea of this task group is to develop enhancements to the current IEEE 802.11 standard to provide a method to configure the distribution system using the four MAC addresses, thereby enabling some form of mesh networking between access points. This could be a wired or wireless mesh network that allows for automatic topology learning and dynamic path configuration over self-configuring multihop topologies. Some proprietary protocols already perform this task to extend coverage within homes, but the standard will allow for different scenarios with different requirements (e.g., quick setup and teardown, maximizing throughput).

Task Group Y: This newly formed task group is looking at operation in the 3.5-GHz bands that were recently

opened by the FCC for WLAN operation. One objective of this protocol is to develop a fair contention protocol for access to the medium.

Although not directly changing or adding to the standards, there are task groups that are involved in maintenance and other issues related to 802.11. Task Group M is performing the maintenance of the 802.11 standard. A Task Group D is looking at regulatory domain updates. There are also new proposed activities that are pending approval at various levels as of the time of the writing: for example, an 802.11t that aims to recommend practices for wireless performance prediction, an 802.11u that is considering interworking with external networks, an 802.11v for network management of mobile stations, and an 802.11w that provides protection (data integrity and authentication) of management frames. In addition, several study groups are looking at harmonizing the 802.11 and the European ETSI standards, and some are investigating the possibility of improvements to the 802.11 standard to provide higher throughput.

Other IEEE and Industry-Based Wireless Standards

The IEEE and other industry consortiums also have developed other wireless standards that are related to WLANs, but not as local area networking standards. The IEEE 802.15 standard looks at *personal area networks* (PANs), or networks related to an operating space around one person. Examples of PANs are Bluetooth networks (Haartsen and Mattisson 2000). In fact, 802.15 is based on Bluetooth. Like 802.11, there are many subcategories of standards in 802.15. One subcategory called 802.15.4 is also commercially popular with some higher layer implementation as the ZigBee standard. The 802.15.3 standard is considering high-speed physical layers that use ultrawideband. The HomeRF standard employs a protocol called *shared wireless access protocol*, which has many similarities with the 802.11 MAC and PHY layers. HomeRF is often considered a PAN standard like Bluetooth. Another IEEE wireless standard is the 802.16 standard (WiMAX) that looks at fixed wireless access. In this case, the goal is to provide fixed broadband wireless links to organizations and residences. These broadband links would replace the last-hop copper or coaxial cable and provide Internet access, video, and telephone services to the customer.

CONCLUSION

In this chapter, an overview of worldwide wireless local area networking standards was provided with a detailed consideration of the IEEE 802.11 standard and its many extensions. A top-down approach was used to describe how networks based on IEEE 802.11 operate. Details of many of the frames at the medium access control layer and the various standard physical layer alternatives were presented. A discussion of the security aspects included in the IEEE 802.11 standard followed by a summary of the many working groups involved in the standardization of IEEE 802.11 completed the chapter.

GLOSSARY

Advanced Encryption Standard (AES): The encryption algorithm used in the latest security standard for 802.11.

Advanced Mobile Phone System (AMPS): The very first cellular telephone service in the United States.

Clear to Send (CTS): Command used by an 802.11 mobile station to indicate to all other mobile stations in its receiving range about a pending transmission; helps reduce the hidden terminal problem and acknowledge an RTS packet.

Complementary Code Keying (CCK): A modulation and encoding scheme used in the 802.11b standard to increase the data rate from 2 Mbps to 11 Mbps while maintaining the original chip rate of 11 Mcps.

Counter Mode Cipher Block Chaining MAC Protocol (CCMP): Message authentication method for ensuring confidentiality and authentication in 802.11i that uses the advanced encryption standard.

Direct Sequence Spread Spectrum (DSSS): A modulation technique used in the original 802.11 standard that spreads the spectrum and provides robustness against multipath.

Distributed Coordination Function (DCF): The basic medium access method in all 802.11 networks; uses carrier sense multiple access with collision avoidance.

Interframe Space (IFS): The waiting time of 802.11 mobile stations to assist in collision avoidance. Different values are used for acknowledgements, regular frames, and polling frames.

Multiple-Input Multiple-Output (MIMO): A method of increasing the capacity of wireless links by using multiple antennae at both transmitter and receiver.

Network Allocation Vector (NAV): A number used by mobile stations to back off (stop sensing the medium) based on information about the length of current transmissions.

Orthogonal Frequency Division Multiplexing (OFDM): The modulation scheme used in 802.11a and 802.11g standards. It splits the channel into many narrow subcarriers, thereby avoiding problems related to the coherence bandwidth of the radio channel.

Point Coordination Function (PCF): An optional polling medium access mechanism that is not widely deployed in 802.11 systems.

Request to Send (RTS): Frames used by an 802.11 mobile station to indicate to all other mobile stations in its receiving range about a pending transmission and reduce the hidden terminal problem.

Wired Equivalent Privacy (WEP): The weak security protocol used in legacy 802.11 systems that made use of the RC4 stream cipher to provide confidentiality and authentication in ways that did not make the system secure.

DIGITAL COMMUNICATIONS OVER FADING CHANNELS

Digital communications is an integral part of modern society, encompassing point-to-point communications, broadcast, and storage. Because of user mobility and ease of use, wireless communications is increasing at a rapid pace. This is fueled by new algorithms, new devices, and new applications. Costs are decreasing and the available content grows richer. Today we can envision digital video over wireless links received on handheld devices.

Digital communications has its modern origins in information theory, developed by Claude Shannon of Bell Labs in the late 1940s. Shannon thought of communications geometrically and spawned the advent of coding for reliable communications over noisy channels. His fundamental insight was the existence of the channel capacity, which represents the ultimate limit of data communications over the channel. The capacity depends on the signal-to-noise ratio, the available bandwidth, and the noise and fading characteristics of the channel. Early work focused on the additive white Gaussian noise (AWGN) channel and was later extended to cover wireless situations. Subsequent to the discovery of information theory, many researchers began the search for codes that could realize Shannon's ideal of reliable communications. Early block codes included those developed by Richard Hamming, Irving Reed, and Gus Solomon. These are still used in some applications today. Convolutional codes were introduced by Peter Elias. Much of these advanced signal processing techniques were ahead of their time and awaited the digital revolution in integrated circuits. At the same time and place as Shannon, John Bardeen, William Shockley, and Walter Brattain, fellow scientists at the Bell Telephone Laboratories in Murray Hill developed the transistor—later extended to the basic integrated circuit, the building block of all current digital communications technology.

A digital communication system, in the abstract, is measured by several metrics. These measure the data efficiency, the bandwidth efficiency, and the energy efficiency, and are measured by the data rate (R_b in bits/sec), bandwidth (W in Hz), and required energy-to-noise ratio (E/N_o in dB), to meet a prescribed bit error rate (BER).

The data rate measures the amount of information that flows to the receiver per unit time. For wireless systems,

this is constrained by available bandwidth, and so is better quantified in terms of spectral efficiency. This is a normalized bit rate by the occupied bandwidth. In work that focuses on the physical layer, all the transmitted data is assumed to have been compressed so that the bit rate represents the information rate.

These bits may not arrive without errors; this is quantified by the BER, or probability of bit error, the major performance metric used in evaluating systems. The key dependence is a measure of energy efficiency, or effective signal-to-noise ratio. In digital communications, this is more correctly written as an energy ratio, E/N_o . This is the required energy-to-noise ratio to achieve a target BER.

Communication systems have two fundamental approaches to increase data rate. They can either transmit signal with higher bandwidth, or use a larger constellation to transmit multiple bits per symbol. Both methods are used in practice. However, an improved data rate comes at a price, a required increase in E/N_o . Coding, as predicted by Shannon, counteracts this trend by combining or encoding large groups of data in blocks. Although this allows for increased efficiency, it drives the complexity of the decoder. It also imposes delay or latency on the receiver, because bits are not put out until the entire block is decoded. Finally, the computational complexity of the system, especially at the receiver, is critical and has to meet implementation constraints. As we examine bit-interleaved coded modulation (BICM) for communications over fading channels, we will encounter all of these trade-offs.

The basic block diagram for digital communications, at its simplest level, involves three parts: the transmitter that carries out the encoding, the channel that forwards the message introducing noise and other impairments, and the receiver that reads the signal and attempts to decode the transmitted data. Outside of this framework, or further up the protocol stack, are the many networking functions that coordinate the messaging from an application viewpoint. Here we are concerned only with the physical transmission across the channel; the PHY layer, in networking terminology. Flow control, routing, acknowledgement receipts, and even data compression are outside the scope of this chapter but are discussed in many other chapters of this handbook.

The digital communications transmitter we will consider consists of several stages. First, the incoming (compressed) bit stream is encoded using a convolutional encoder. Codes of different strengths can be employed, but nominally a rate 1/2 code is used. This encoder puts out two encoded bits for each input bit. The definition of the encoder can be found in many textbooks on digital communications (Proakis 2000). The output bits are interleaved, or permuted, over a large block, usually on the order of thousands of bits. The bit interleaver is the novel item in the BICM transmitter. It serves to break the channel correlation as well as spread the coded bits in the block to facilitate decoding. Following the bit interleaver, the bits are grouped and mapped to complex symbols to prepare for transmission. We focus on 16-quadrature amplitude modulation (QAM) and 8-phase shift keying (PSK) constellations in our review of BICM, although it is indeed possible to go to larger alphabets. Increasing the alphabet size, 16-QAM being determined by a labeling of four coded bits to each symbol, generally increases the data rate. The energy efficiency decreases, and the susceptibility to system imperfections increases. A more complete discussion of the BICM code properties will follow this system overview. Finally, the transmitter pulse shapes and modulates the symbols to the appropriate carrier frequency and bandwidth. These latter components are standard to any digital pulse amplitude modulator and are discussed by Proakis (2000). This description holds for a single-carrier modulation scheme, but can be extended to multi-carrier approaches using orthogonal frequency division multiplexing (OFDM). OFDM is used in some flavors of wireless fidelity (WiFi) (802.11a,11g,11n) and Worldwide Interoperability for Microwave Access (WiMAX) (802.16,16a,16d). Since OFDM can compensate for delay-spread multipath and eliminate intersymbol interference, we will assume this structure in order to focus on design and performance of the coded modulation.

An overall block diagram of a generic digital communication system is shown in Figure 1. This shows the basic functionality required in the transmitter and receiver, and lists some basic impairments introduced by the channel. A complete system design is beyond the scope of our discussion here.

The primary issues will include the design of:

1. The encoder. A convolutional code is used.
2. The bit interleaver. Not shown, but pseudo-randomly permutes a large block of ($\approx 10^4$) coded bits.
3. The digital modulator. M -ary PSK or QAM is used. Space-time coding is also considered. The mapping of bits to symbols is critical.

4. The channel. A slow, flat fading channel.
5. The receiver. Primary emphasis is on design and performance of the iterative decoder. Synchronization, limited to the extraction of channel state information (CSI), is also considered.

Ultimately, the system is evaluated against the metrics listed. However, many functions are neglected in our discussion. These items would include mostly the analog interfaces such as pulse shaping, radio frequency (RF) transmitter and receiver, and synchronization beyond CSI extraction (timing, frequency, phase, etc.). They are critical to real-world performance but beyond the scope of our discussion.

We illustrate the coherent modulation formats that we will employ in Figure 2. Three constellations are shown in each row, corresponding to a member of the PSK (top) or QAM (bottom) family. The leftmost member is always the binary antipodal constellation in which 1 bit of information is conveyed per transmitted symbol. As we progress across the family, the bit rate increases, but the symbol rate remains fixed. The main examples we will present in this chapter are the last family members: 8-PSK (three bits/symbol) and 16-QAM (four bits/symbol). The QAM family has better performance but is more difficult to implement due to increased sensitivity to nonlinear distortions. The actual transmitted waveform is a mapping from the selected constellation point to an analog waveform. The details are important in system design but not critical for an assessment of BICM.

BICM employs coded modulation in which the transmitted symbol is a mapping of coded bits. The encoder is shown in our block diagram and will actually consist of two sequential operations—a convolutional encoder followed by a bit interleaver. The convolutional encoder is one technique to introduce redundancy into the information bit stream. Information theory shows that this is required to allow for error correction and reliable communications. Many codes are employable, and this is an active research area. We will discuss convolutional codes in more detail, but it is possible to replace this with more powerful turbo or low-density parity check (LDPC) codes. These more powerful codes substantially increase the complexity and change the design rules; they are beyond the scope of this chapter. Convolutional codes are widely used in commercial systems, and chipset encoders and decoders are readily available. As we will see, these are not suitable for the best performance obtainable with iterative decoding using soft feedback. They are suitable for lower performance hard-decision decoding.

The convolutional code is described by its code rate and encoder structure. The code rate $R_c = k_c/n_c$ is the ratio of

Figure 1: Block diagram for a generic digital communication system

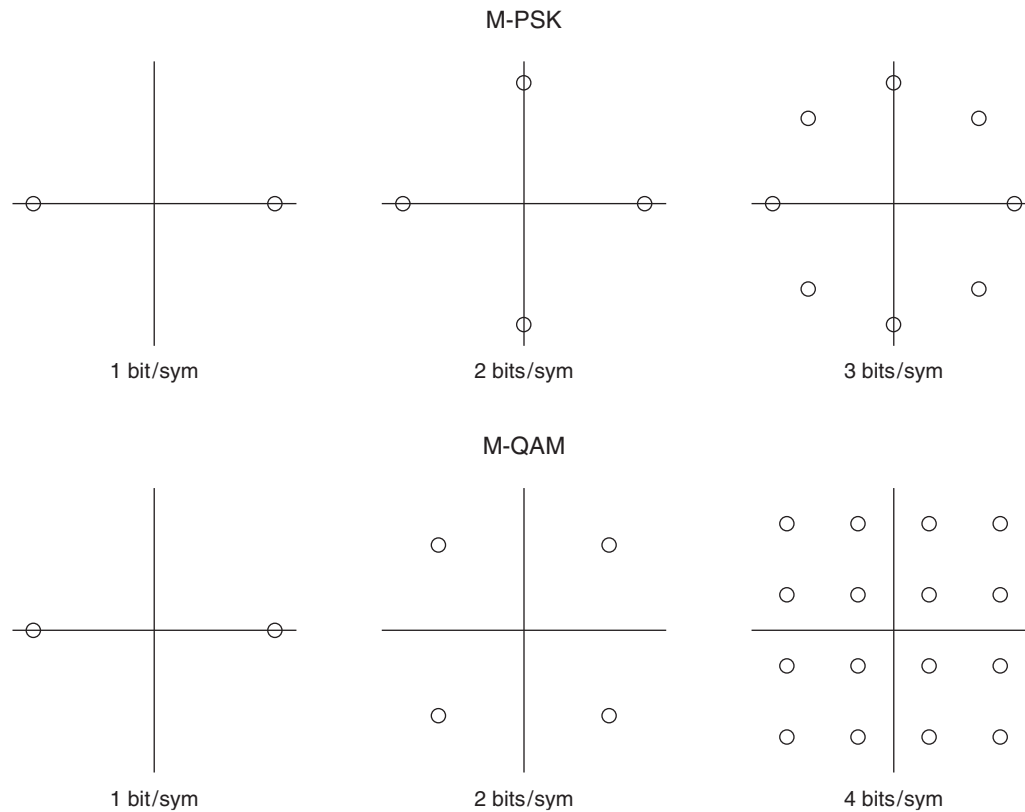

Figure 2: *M*-PSK (top) and *M*-QAM (bottom) constellations

the number of information bits put in, k_c , to the number of coded bits put out, n_c . A typical value is $1/2$, which puts out two coded bits for every input information bit. This redundancy allows for error-correcting capability if the code is properly designed. However, the two output bits would need to be sent in the time period of the single input bit. This can be accomplished in one of the two ways: either by increasing the required bandwidth by signaling faster at the same information rate or by decreasing the information rate to accommodate the redundancy. This fundamental trade-off can be circumvented in our coded modulation structure. The two coded bits can be mapped to a single complex constellation point drawn from, say, 4-QAM. This holds both the bandwidth and information rate fixed. The design of these coded modulation systems, called trellis-coded modulation or TCM, was completed in the late 1980s and was critical to the design of high-rate voice-band modems. Today, these are still employed on specific channels. In BICM, the best convolutional codes of a given constraint length are employed. The constraint length can be viewed as a measure of complexity. One key difference between BICM and TCM is that, in TCM, the coding and modulation are jointly designed. In fact, the bits that are used to make up a constellation symbol can be grouped into two segments: those that are coded and those that are not. In contrast, BICM, through the random interleaving, separates coding and modulation. Capacity analysis has shown that BICM is nearly optimal over perfectly interleaved Rayleigh channels and performs very well over AWGN channels as well.

This robustness is an important practical advantage for BICM, because realistic wireless channels can vary over time and exhibit more or less fading for fairly long periods. We also mention multilevel coding with multistage decoding, which is an alternative design to both TCM and BICM. This appears slightly superior in performance, at the cost of some complexity. BICM-ID with very high performance turbo or LDPC codes appears to offer the best performance at a reasonable cost at present.

The channel introduces noise and distortion onto the received signal. The noise is commonly modeled as additive, uncorrelated, and Gaussian, and arises from several sources. All receivers introduce front-end thermal noise from the electronics, and this suffices to motivate AWGN. The transmitted signal is heavily attenuated during propagation, the signal loss going as the inverse square of the transmitted distance. This transmission loss is increased at higher frequencies and can be further shadowed by non-line-of-sight (NLOS) propagation. As the wireless signal propagates in real-world scenarios, fading occurs. Fading is the destructive interference that results from the reflection of several electromagnetic ray paths from scattering objects. The variation in received signal level fluctuates, so that a statistical model is often used to design and evaluate digital communication systems. For various reasons beyond the scope of this chapter, we can assume slow, flat fading, which models the fluctuating attenuation as a random variable, constant over the duration of any symbol, while changing abruptly from symbol to symbol. The degree to which the attenuation changes, the

temporal correlation, is determined by the relative velocity of the transmitter, receiver, and scatterers themselves.

A commonly accepted model is the Rayleigh fading model, in which the signal phase is completely randomized while the amplitude suffers a random attenuation modeled as a sample from the Rayleigh distribution. It models diffuse propagation in which no single propagation path dominates the totality of all paths. A more complex model, which we will illustrate, is the Ricean fading model, named after Stephen O. Rice, another Bell Lab researcher who developed much of modern noise theory in a significant paper published in the *Bell Systems Technical Journal*. Ricean fading can be described as a dominant path in the presence of a diffuse set of paths. The distribution is parameterized by the ratio of the energy in the dominant to diffuse paths, the K factor. The Ricean distribution for various values of K is shown in Figure 3. Many additional statistical models for fading have been developed for wireless channels. The correct model depends heavily on the terrain (urban/suburban/rural), the frequency band, and the mobility. The system designer is faced with developing an effective system that works in spite of the channel and does not rely on any particular assumptions. The Rayleigh model is the most conservative choice.

In the case of Ricean fading, the fading intensity per channel v_i has probability density function

$$f(v_i) = (K+1)e^{-K-(K+1)v_i} I_0\left(2\sqrt{K(K+1)}v_i\right) \quad (1)$$

where I_0 is a special mathematical function called the modified Bessel function of order 0. This probability density function is scaled to unit mean and parameterized in terms of the Ricean factor K , the ratio of specular to diffuse power.

The impact of fading on digital communications can be illustrated for binary phase shift keying (BPSK) over a Rayleigh fading channel. Assume a discrete time model of the received matched filter output at symbol t is given by

$$r_t = \alpha_i \sqrt{E} s_t + n_t \quad (2)$$

Figure 3: Ricean fading probability density functions

where s_t is the symbol, E is the energy per symbol, and n_t is a white Gaussian noise (WGN) sample of variance $N_0/2$ per dimension. The remaining factor α represents the channel attenuation. It will model the complex Rayleigh fading. Assuming perfect phase compensation, the BER is given by

$$P_e = Q(\sqrt{2S|\alpha|^2}), \quad S = E/N_0. \quad (3)$$

The Q -function is the right tail of the normal distribution and is often approximated in digital communications by $Q(\sqrt{2S|\alpha|^2}) \approx \exp(-S|\alpha|^2)$. Note that the BER decays exponentially fast in $S = E/N_0$.

Next, consider the fading situation. Now the $|\alpha|$ is Rayleigh distributed and the earlier result is only conditional, and must be further averaged over the fading distribution. Carrying out the integration defines a new average probability of error given by

$$\bar{P}_e = \int Q(\sqrt{2Sv}) f(v) dv \sim 1/4S. \quad (4)$$

The key feature is the behavior of the BER curve, in particular, how rapidly it decays for large values of signal-to-noise ratio (SNR). The decay rate is exponential in the SNR. What is the effect of the fading upon this error-rate characteristic? It is to change this rapid exponential decay into a slow algebraic decay so that, in Rayleigh fading, the BER decays only as the inverse of the SNR. Without fading mitigation, this causes losses on the order of about 30 dB.

The mitigation takes the form of diversity combining, in which multiple symbols are sent over independent channel realizations and coherently combined to average out the fading. The multiple symbols can be obtained in many ways: multiple antennas, repeated symbols, or frequency slots. These are generally less efficient than interleaving the coded symbols and sending them across effectively independent fading channels. The independence is achieved because the symbols are spread far apart in time, relative to the fading rate. The end result is that the slope of the log-BER characteristic changes from 1 to the "diversity order" L . More precisely (Proakis 2000),

$$\bar{P}_e \sim C_f (4S)^{-L}, \quad C_f = \left(\frac{2L-1}{L} \right). \quad (5)$$

Here L is the number of independent symbols used in the combining, and C_f is a multiplicative constant. The actual value of the diversity order in more complicated scenarios depends on the fading correlation and signaling scheme.

BIT-INTERLEAVED CODED MODULATION

Next, we apply these general principles to conventional BICM. We will model BICM as the serial concatenation of the convolutional encoder, pseudo-random bit interleaver, and memoryless modulator (Caire, Taricco, and Biglieri 1998), as shown in Figure 4.

As we have discussed, the information sequence is encoded by a convolutional encoder before being bitwise

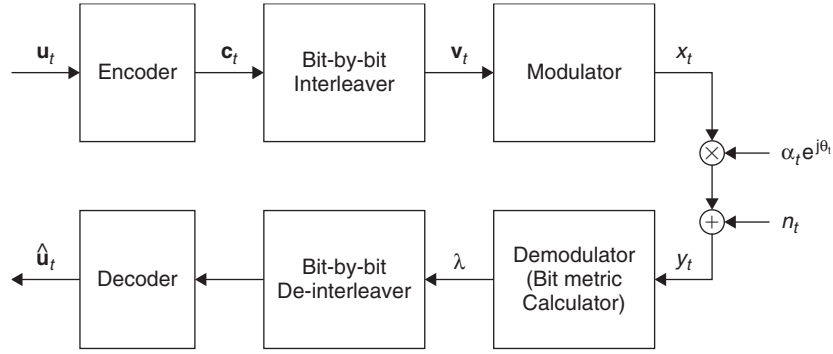

Figure 4: BICM block diagram

interleaved. The purpose of this bit interleaver (π) is to break the fading correlation and increase the diversity order from the minimum symbol distance to the minimum Hamming (bit) distance of a code, as illustrated by Zehavi (1992) and Caire et al. (1998). Then m consecutive bits of the interleaved coded sequence are grouped to form \mathbf{v}_t , a channel symbol at the t -th signaling interval. The modulator maps each \mathbf{v}_t to a complex transmitted signal $\mathbf{x}_t = \mu(\mathbf{v}_t)$ chosen from M -ary constellation χ , where μ is the labeling map and $M = 2^m$. These labeling maps are critical to performance.

As discussed, with an OFDM system, it is reasonable to assume a flat Rayleigh (Ricean with $K = 0$) fading channel with coherent demodulation. The baseband signal at the receiver is

$$\mathbf{y}_t = \alpha_t \mathbf{x}_t + \mathbf{n}_t, \quad (6)$$

where α_t is the Rayleigh-distributed fading coefficient with $E(\alpha_t^2) = 1$, and \mathbf{n}_t is a complex white Gaussian noise sample with the variance of $N_0/2$ per dimension. For the AWGN channel, $\alpha_t = 1$. Throughout this section, we will assume perfect CSI so that α_t is perfectly estimated and available to the receiver. We assume perfect knowledge of the phase and that this has been compensated in the receiver model. In practice, this CSI must be estimated from pilot symbols or tones. Later we relax this assumption.

One approach to demodulating conventional BICM is to use the Viterbi algorithm (VA) originally designed for decoding convolutional codes over AWGN channels. This requires a metric for each transmitted symbol, which is built up from metrics for each interleaved bit.

Suboptimal maximum log-likelihood bit metrics (Caire et al. 1998) can be obtained as follows:

$$\begin{aligned} \lambda(\mathbf{v}_t^i = b) &= \log \sum_{\mathbf{x}_t \in \chi_b^i} P(\mathbf{y}_t | \mathbf{x}_t) \\ &\approx \max_{\mathbf{x}_t \in \chi_b^i} \log P(\mathbf{y}_t | \mathbf{x}_t) \\ &= -\min_{\mathbf{x}_t \in \chi_b^i} \|\mathbf{y}_t - \alpha_t \mathbf{x}_t\|^2, \end{aligned} \quad (7)$$

where χ_b^i is the subset of χ whose labels have the binary value b at the i -th bit position. Each bit metric is calculated by selecting the constellation point with the minimum distance over the subset χ_b^i . These branch metrics can be obtained by adding the de-interleaved bit metrics before the Viterbi decoder.

The performance of BICM can be dramatically improved with iterative decoding.

BIT-INTERLEAVED CODED MODULATION WITH ITERATIVE DECODING

The iterative decoding receiver is based on the advances made in the design of turbo decoding algorithms.

We review the soft-decision bit metric calculation for iterative decoding (Li, Chindapol, and Ritcey 2002). Our receiver uses a suboptimal, iterative method through individually optimal but separate demodulation and convolutional decoding steps as shown in Figure 5. The Viterbi decoder is replaced by the soft-input soft-output

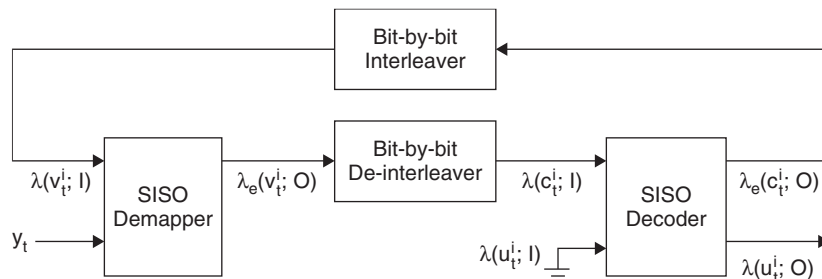

Figure 5: BICM-ID receiver with soft feedback

(SISO) decoder (Benedetto et al. 1997), and the output of the SISO decoder is fed back to the demodulator for bit metric recalculation. At the demodulator, the maximum a posteriori probability bit metrics are calculated as

$$\begin{aligned}\lambda(\mathbf{v}_t^i = b) &= \log P(\mathbf{v}_t^i = b | \mathbf{y}_t) \\ &= \log \sum_{\mathbf{x}_t \in \chi_b^i} P(\mathbf{x}_t | \mathbf{y}_t) \\ &\propto \log \sum_{\mathbf{x}_t \in \chi_b^i} P(\mathbf{y}_t | \mathbf{x}_t) P(\mathbf{x}_t).\end{aligned}\quad (8)$$

The a priori probability $P(\mathbf{x}_t)$ is unavailable on the first pass of demodulation. Therefore, an equally likely assumption is made and equation 7 is used as the input to the SISO decoder, which then generates the a posteriori probabilities for both information and coded bits. Note that the metric shown in equation 7 is just a simplification of equation 8.

Let \mathbf{c}_t denote the de-interleaved version of \mathbf{v}_t and \mathbf{u}_t denote the input symbol corresponding to \mathbf{c}_t . Following the notation of Benedetto et al. (1997), we denote $P(q; I)$ as the a priori probability for a variable q . $P(q; O)$ is the a posteriori probability. Note that $P(\mathbf{u}_t; I)$ is never available because it requires knowledge of the information sequence at the receiver.

On the second pass, the extrinsic, a posteriori probabilities $P(\mathbf{c}_t^i; O)$ put out by the SISO module are interleaved and fed back as the a priori probabilities $P(\mathbf{v}_t^i; I)$ to the demodulator. Therefore, a priori probabilities for equation 8 can be computed by

$$\begin{aligned}P(\mathbf{x}_t) &= P(\mu(\mathbf{v}_t; I)) \\ &= \prod_{i=1}^m P(\mathbf{v}_t^i = \tilde{\mathbf{v}}_t^i(\mathbf{x}_t); I),\end{aligned}\quad (9)$$

where $\tilde{\mathbf{v}}_t^i(\mathbf{x}_t)$ is the value of the i -th bit of the label corresponding to $\mathbf{x}_t = \mu(\mathbf{v}_t)$. Using equation 8 and equation 9, the extrinsic a posteriori bit probabilities for the second pass demodulation can be written as

$$\begin{aligned}P(\mathbf{v}_t^i = b; O) &= P(\mathbf{v}_t^i = b | \mathbf{y}_t) / P(\mathbf{v}_t^i = b; I) \\ &= \sum_{\mathbf{x}_t \in \chi_b^i} P(\mathbf{y}_t | \mathbf{x}_t) \prod_{\substack{j=1 \\ j \neq i}}^m P(\mathbf{v}_t^j = \tilde{\mathbf{v}}_t^j(\mathbf{x}_t); I).\end{aligned}\quad (10)$$

Equation 10 shows that we need only the a priori probabilities $P(\mathbf{v}_t^j; I)$ of the other bits ($j \neq i$) on the same channel symbol \mathbf{v}_t when recalculating the bit metrics. The receiver then uses (10) to regenerate the bit metrics and iterates demodulation and decoding. After the last pass, the final decoded outputs are the hard decisions based on the extrinsic bit probabilities $P(\mathbf{u}_t^i; O)$. This is the total a posteriori because $P(\mathbf{u}_t^i; I)$ is unused.

Signal labeling is the crucial part of conventional BICM and BICM-ID design. It is shown by Caire et al. (1998) that Gray labeling yields the best performance for BICM. They also show that the asymptotic performance of BICM over Rayleigh fading can be approximated by

$$\log_{10} P_b \approx \frac{-d_2(C)}{10} \left[\left(R d_h^2(\mu) \right)_{dB} + \left(\frac{E_b}{N_0} \right)_{dB} \right] + const, \quad (11)$$

where P_b is the probability of bit error, $d_2(C)$ is the minimum Hamming distance of the code, R is the information rate, and $d_h^2(\mu)$ is the harmonic mean of the minimum squared Euclidean distance. For any M -ary constellation with a labeling map μ , $d_h^2(\mu)$ can be calculated by

$$d_h^2(\mu) = \left(\frac{1}{m 2^m} \sum_{i=1}^m \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^i} \frac{1}{\|\mathbf{x} - \hat{\mathbf{z}}\|^2} \right)^{-1}, \quad (12)$$

where $m = \log_2(M)$. Here $\hat{\mathbf{z}} \in \chi_b^i$ is the nearest constellation point to \mathbf{x} .

Therefore, it is obvious that the asymptotic BICM performance over Rayleigh fading depends primarily on the minimum Hamming distance of a convolutional code $d_2(C)$ and the harmonic mean of the minimum squared Euclidean distance $d_h^2(\mu)$. Specifically, $d_2(C)$ controls the slope of the BER curve, and $d_h^2(\mu)$ gives the horizontal offset. Intuitively, the diversity order can further be increased by concatenating the larger signal constellation with a lower-rate code; however, it may not provide a lower P_b in the range of interest due to reduction in the minimum intersignal Euclidean distance among signal constellation points (Caire et al. 1998). Note that a labeling map μ is independent of a convolutional code C due to bit interleaving; therefore, it can be separately optimized in our iterative decoding algorithm without altering the code diversity. This is carried out to maximize the harmonic mean of the minimum Euclidean distance as seen with error-free feedback.

Next we repeat the analysis for BICM-ID. The reader will notice that, through feedback, information about other bits in the symbol can be used to reduce the error possibilities during decoding, as compared with BICM. As shown by Chindapol and Ritcey (2001), the asymptotic performance of the error floor of BICM-ID is obtained by

$$\log_{10} P_b \approx \frac{-d_2(C)}{10} \left[\left(R \tilde{d}_h^2(\mu) \right)_{dB} + \left(\frac{E_b}{N_0} \right)_{dB} \right] + const, \quad (13)$$

where

$$\tilde{d}_h^2(\mu) = \left(\frac{1}{m 2^m} \sum_{i=1}^m \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^i} \frac{1}{\|\mathbf{x} - \tilde{\mathbf{z}}\|^2} \right)^{-1}. \quad (14)$$

Note that $\tilde{\mathbf{z}}$ is the only member in χ_b^i , so the opportunities for errors are greatly reduced as compared with BICM, which suffers from "random modulation." Because there is no change in the coding structure or constellation size, all terms on the right hand side of equation 11 and equation 13 are the same except that $\tilde{d}_h^2(\mu)$ substitutes for $d_h^2(\mu)$. Therefore, from equation 12 and equation 14 the labeling map μ should be designed such that $\|\mathbf{x} - \tilde{\mathbf{z}}\|$ is larger than $\|\mathbf{x} - \hat{\mathbf{z}}\|$ for all \mathbf{x} (if possible) in order to achieve the iterative decoding gain. In other words, iterative decoding feeds back information about the other bits that can be used to reduce the error probability.

Figure 6 shows the subset partitioning for each of the four bit positions of the 16-QAM constellation. Define χ_b^i

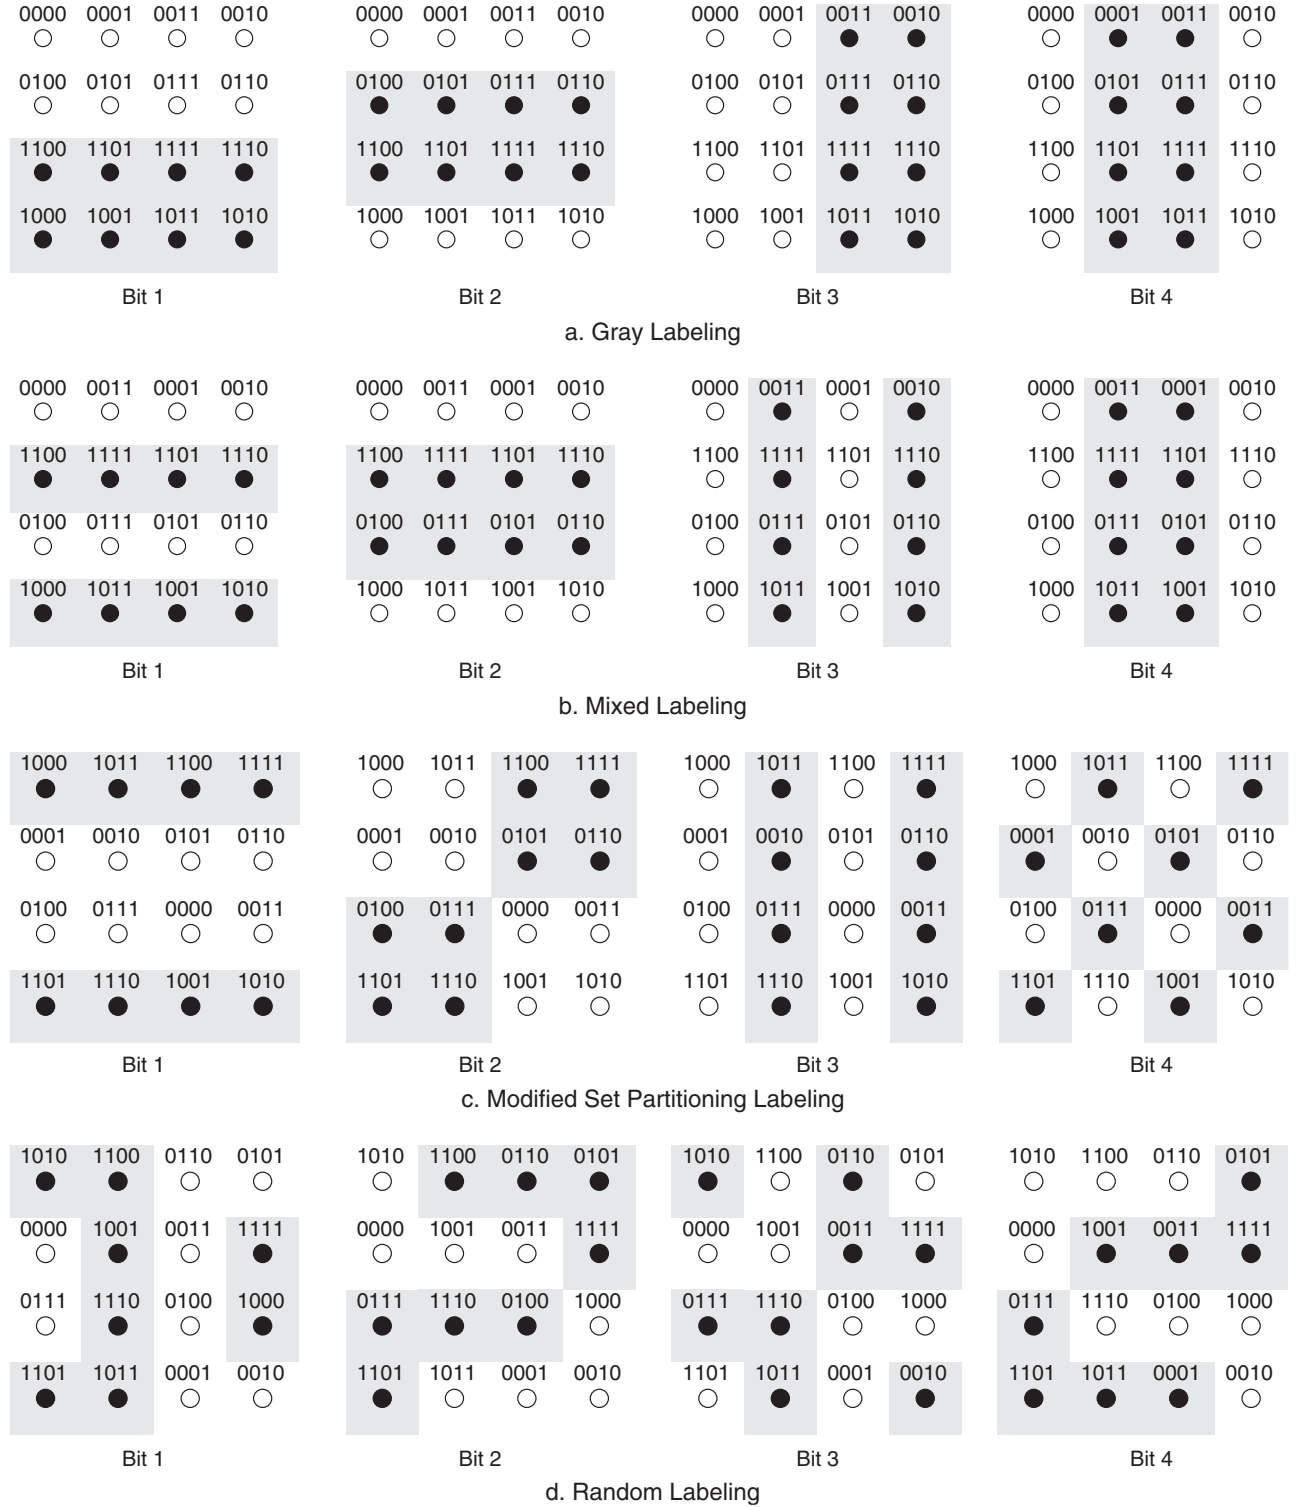

Figure 6: Subset partitions of 16-QAM for four labeling schemes

to be the subset of the constellation points for which bit i takes on value b . For example, χ_1^1 is the subset for which bit $i = 1$ takes on value $b = 1$. The shaded regions (only shown inside the unit square) correspond to the decision regions for each bit in χ_1^i , and the unshaded to χ_0^i . It is obvious that all labeling methods have the same

minimum Euclidean distance between subsets of χ_1^i and χ_0^i but a different number of nearest neighbors.

Given ideal feedback of all other bits, a 16-QAM constellation is translated to a binary signaling selected from eight possible pairs. Figure 7 illustrates the increase in the minimum Euclidean distance between subsets.

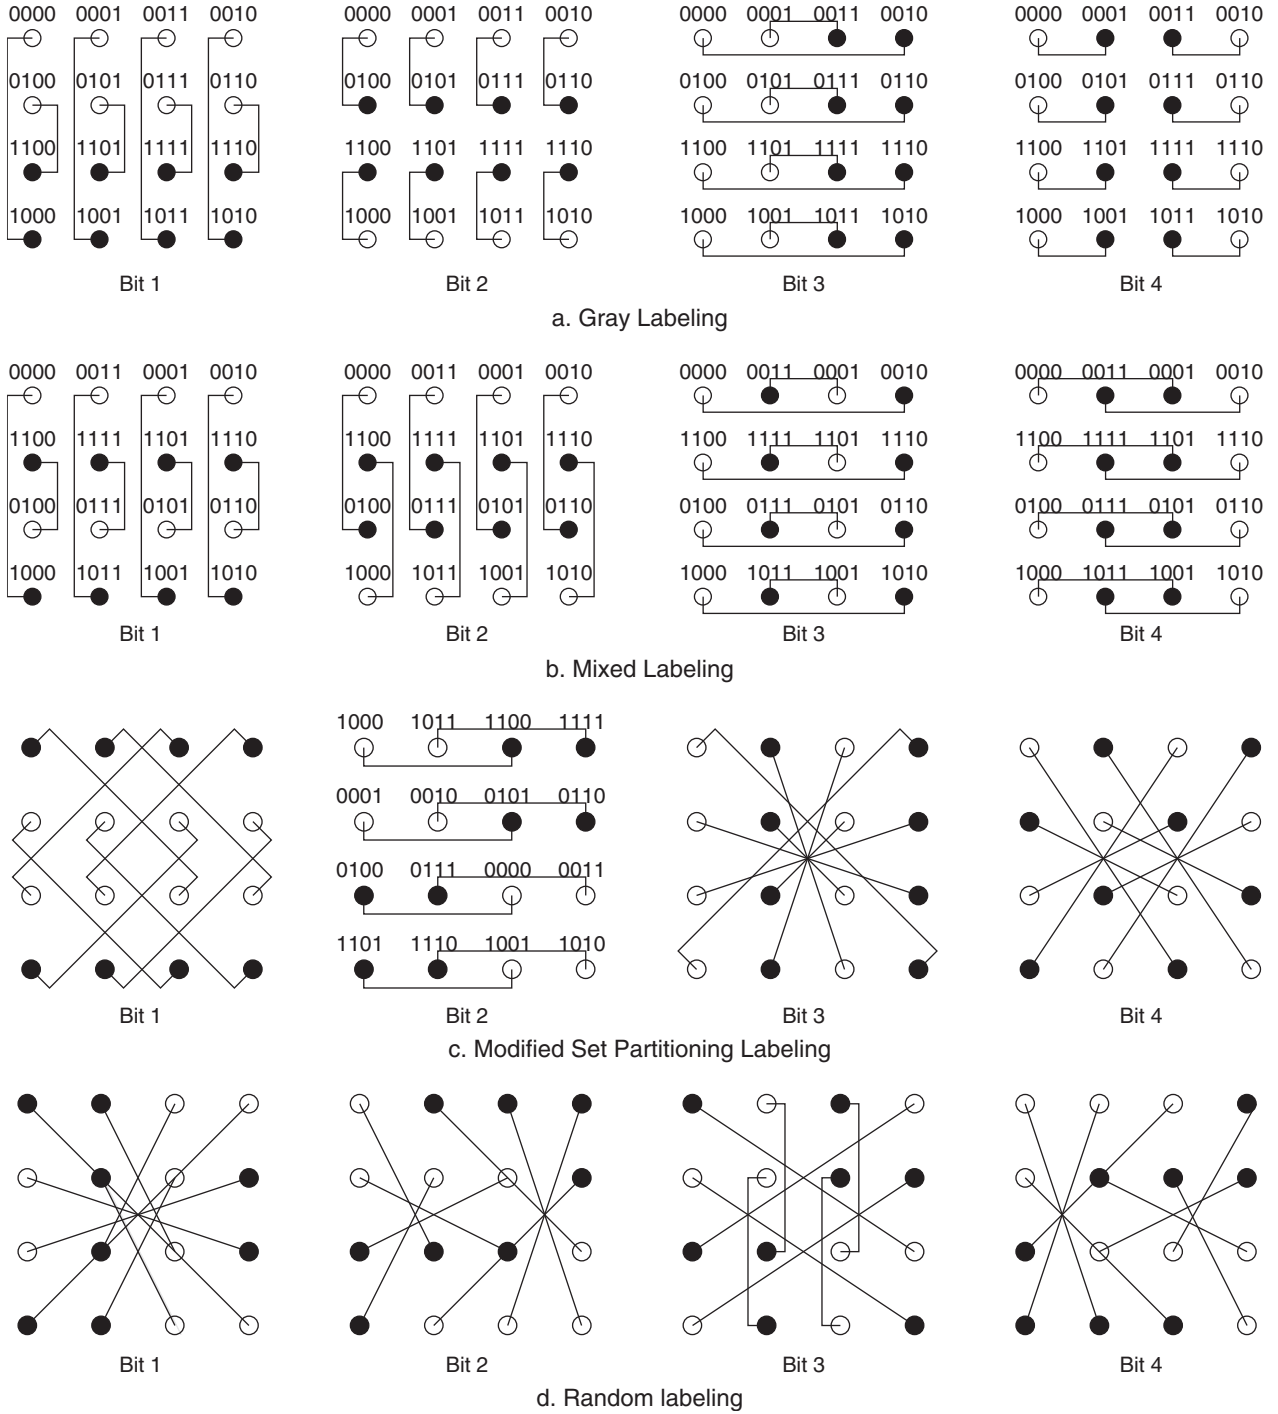

Figure 7: 16-QAM channel is converted to eight binary channels, each selected by the other three ideal feedback bits

Gray labeling is not the preferred choice because most binary signal sets resulting from ideal feedback have the same intersignal Euclidean distance as the original 16-QAM constellation.

Numerical results from calculating the *harmonic* mean of the minimum Euclidean distance before feedback, d_h^2 , and after feedback, \hat{d}_h^2 , are shown in Table 1. We call the difference in $(\hat{d}_h^2)_{dB}$ and $(d_h^2)_{dB}$ of conventional BICM with Gray labeling the *offset gain*.

This gives a quick comparison between various labeling schemes with iterative decoding and conventional BICM. In addition, optimization of $d_h^2(\mu)$ is done separately from our decoding algorithm; therefore, the *offset gain* is the asymptotic performance improvement regardless of the code structure. It is preferable to have a labeling map that maximizes $\hat{d}_h^2(\mu)$ while having sufficiently large original $d_h^2(\mu)$ such that the feedback decoder can reach its ideal performance within a few passes.

Table 1: Comparison of the Harmonic Mean of the Minimum Euclidean Distance before (d_h^2) and after Ideal Feedback (\tilde{d}_h^2), and Differences in the Values of $(\tilde{d}_h^2)_{dB}$ and $(d_h^2)_{dB}$ of Gray Labeling

Labeling	d_h^2	\tilde{d}_h^2	Offset Gain (dB)
Gray	0.492	0.514	0.19
Random	0.413	2.602	7.23
Modified SP	0.420	2.279	6.65
Mixed	0.400	0.993	3.05
SP	0.441	1.119	3.56

Consider the impact of signal labeling on the offset gain. For BICM-ID with the same convolutional code, Table 1 shows that Gray labeling yields the best performance without feedback due to the largest d_h^2 ; however, the performance gain with feedback is very small. Random labeling gives the largest \tilde{d}_h^2 and thus the largest asymptotic offset gain at the cost of having the poorest first-round performance. Modified set partitioning (MSP) labeling shows a good compromise between the first-round performance and the asymptotic iterative decoding performance. Although mixed labeling does not show large feedback gain, Figure 7 shows that only one bit from the feedback affects the decoding result; therefore, mixed labeling is robust to feedback error when hard-decision feedback is used. The weaker performance improvement obtained by using Ungerboeck's set partitioning (SP) labeling (1982) over fading channels is also shown for comparison.

BICM WITH JOINT ITERATIVE CHANNEL ESTIMATION AND DECODING

So far we have studied BICM and BICM-ID over fading channels with perfect CSI at the receiver. For mobile communication systems with time-varying channel response, CSI is crucial in achieving the expected decoding performance of a channel code. To obtain CSI, pilot symbol assisted modulation (PSAM) has been proposed and proven to be effective for Rayleigh and Ricean fading channels (Cavers 1991). The transmitter periodically inserts known symbols, from which the receiver estimates channel amplitude and phase reference.

Because BICM-ID is a high-performance coded modulation that ideally operates in a very low SNR region, traditional channel estimation techniques, such as PSAM, can induce large estimation error. As an example, we consider a mobile communication system that employs BICM-ID and PSAM over Rayleigh fading channels. The symbol rate is 16k symbols/s and the Doppler is 100 Hz, which gives the normalized Doppler spread $f_d T_s = 6.25 \times 10^{-3}$. The speed of the mobile station (MS) is about 120 km/h (75 MPH) with carrier frequency 900 MHz, or 60 km/h (37.5 MPH) with carrier frequency 1.8 GHz. The BICM-ID

Figure 8: Performance of 16-QAM BICM-ID with perfect CSI and PSAM over Rayleigh fading. The low-pass sinc interpolator is used for PSAM. The best 16-state rate 1/2 convolutional code and MSP labeling with soft feedback are used

scheme uses 16-QAM MSP labeling (Chindapol and Ritcey 2001) with the best 16-state rate 1/2 convolutional code (Lin and Costello, Jr. 1983). The low-pass sinc interpolator is used in the PSAM channel estimation. Figure 8 compares the BER performance of this system using PSAM channel estimation with that of an ideal system with perfect CSI, in which about 1.6 dB degradation for each iteration is observed. The star-marked dashed curve shows the asymptotic BER performance predicted by the error-free feedback (EF) bound of BICM-ID with imperfect CSI (Huang and Ritcey 2003). For a given interleaving depth, the quality of channel estimation becomes the limiting item in system performance of BICM-ID (Huang and Ritcey 2003).

A similar problem also exists in turbo coding (Berrou and Glavieux 1996). As a promising solution, joint channel estimation and decoding has been explored, and iteratively filtered PSAM (IF-PSAM) is proposed and studied by Valenti and Woerner (2001) and Su and Geraniotis (2002) for turbo codes with BPSK modulation. Figure 9(a) illustrates the basic schedule for IF-PSAM, which alternates channel reestimation and decoding. The pilot symbol filter (PSF) performs initial channel estimation based on the received pilot sequence, and, after each turbo decoder iteration, the tentatively decoded data symbols are also fed back into the all symbol filter (ASF) to produce refined channel estimates.

As analyzed by Huang and Ritcey (2005c), IF-PSAM algorithm can introduce severe error propagation problems when directly applied to BICM-ID. In early decoding passes of BICM-ID, channel reestimation can be degraded because there are too many errors in the tentative decoding results. The decoder will be locked in a local minimum and never converge to the zero-error state. In such cases, channel reestimation after *each* iteration is neither beneficial nor efficient.

To solve the error propagation problem, a multistage algorithm, named sparsely interleaved estimation and decoding (SIED), was developed by Huang and Ritcey (2005c).

Figure 9: Illustration of the classical IF-PSAM algorithm and the recently proposed SIED algorithm for joint iterative channel estimation and decoding, showing the pilot symbol filter (PSF) and all symbol filter (ASF) alternating with the decoder (DEC)

In SIED, as shown in Figure 9 (b), decoding proceeds until the current decoder stage converges so that the decoding potential is *fully* exploited, and only then the decoder feeds back the best achievable decoding results for reestimation. Decoder convergence can be detected by keeping track of the soft decoding metrics (SDMs) proposed by Wang and Parhi (2002). Compared to IF-PSAM, the SIED algorithm improves performance with increased efficiency because unnecessary channel reestimation is avoided.

As a numerical example, Figure 10 compares the simulated BER of SIED algorithm and the classical IF-PSAM algorithm over correlated Rayleigh fading channel with normalized Doppler $f_d T_s = 0.05$. The results shown for IF-PSAM is at the fifteenth iteration; the results for SIED are from the last iteration (less than fifteen iterations) because early termination is also implemented. The solid lines are for the case with 10^5 information bits per block, and the dashed lines are for a shorter block size of 10^4 information bits. For both cases, we can clearly see that SIED outperforms the other algorithm by extensively exploiting the soft decoding output and a much-improved reestimation schedule that avoids error propagation. The SIED algorithm has about 0.5 dB improvement in E_b/N_0 over IF-PSAM.

To analyze the asymptotic BER of BICM-ID, the error-free feedback bound (EF bound) with imperfect CSI

(Huang and Ritcey 2003) is also shown as reference. This bound is computed based on the assumption that the data symbols are perfectly decoded and fed back to the ASF for channel reestimation (Huang and Ritcey 2005c). As we observe, when E_b/N_0 is large enough, the BER curves for both the SIED and IF-PSAM algorithms can approach the EF bound very closely. However, the SIED algorithm requires a much lower E_b/N_0 than IF-PSAM to break the barrier of the initial channel estimation error and trigger the convergence to the ideal asymptotic performance.

BIT-INTERLEAVED SPACE-TIME CODED MODULATION WITH ITERATIVE DECODING

High-data-rate applications are considered one of the most important future breakthroughs in wireless communications, and also a very challenging goal, particularly for systems that are power, bandwidth, and complexity limited. Motivated by the need for high spectral efficiency, the use of multiple transmit and receive antennas has been extensively exploited to significantly increase channel capacity. Pioneering works by Telatar (1995) and Foschini (1996) predict remarkable spectral efficiencies

Figure 10: Comparison of the BER performance of SIED and IF-PSAM with different block sizes, over correlated Rayleigh fading channel with $f_d T_s = 0.05$. The asymptotic BER is predicted by the EF bound for the ASF with ideal feedback. The SNR limit is obtained from the BICM capacity results with imperfect CSI over uncorrelated Rayleigh fading channels

for multiple-input multiple-output (MIMO) systems. It has been shown by Telatar (1995) that the theoretical capacity increases linearly with the minimum number of the transmit and receive antennas when there is rich scattering and the channel variation can be accurately tracked.

On the other hand, the use of multiple transmit and receive antennas provides higher diversity order that can be exploited to combat severe attenuation in a multipath wireless environment. The designs of space-time codes for achieving these advantages include the Bell Laboratories layered space-time (BLAST) architecture (Foschini 1996), the trellis codes (Tarokh, Seshadri, and Calderbank 1998), and the orthogonal designs (Tarokh, Jafarkhani, and Calderbank 1999b). Bit-interleaved space-time coded modulation (BI-STCM) was proposed by Hong and Hughes (2001) as an effective approach to capture both space and time diversity.

In light of the conventional BICM-ID (Chindapol and Ritcey 2001; Li et al. 2002), in this section we consider BI-STCM with iterative decoding (BI-STCM-ID) over fast Rayleigh fading MIMO channels. A general, tight, and efficient error-free feedback bound (EF bound) is developed to analyze the asymptotic BER of BI-STCM-ID (Huang and Ritcey 2004). The design criterion is also proposed to achieve the largest asymptotic coding gain inherited in the constellation labeling (Huang and Ritcey 2005b). For orthogonal space-time block codes (STBCs), Huang and Ritcey (2005b) showed that the labeling optimization problem can be solved as a quadratic assignment problem (QAP). Numerical results show that the optimal labeling maps achieve significant improvements in the asymptotic coding gain for both the 16-QAM and 64-QAM constellations.

Figure 11(a) shows the block diagram of the BI-STCM transmitter, which is a serial concatenation of the conventional BICM (Caire et al. 1998) and an STBC \mathcal{G} whose entries are linear combinations of the variables s_1, \dots, s_q and their conjugates (Tarokh et al. 1999b). The information bit sequence is first encoded by a convolutional code of rate $R_c = k_c/n_c$. Then the encoder output is bit-interleaved (B-ITL) and each $K = mq$ bits of the interleaved sequence are grouped as a channel symbol $\mathbf{v}_t = [v_t^1, \dots, v_t^k, \dots, v_t^K] = [\mathbf{v}_t^1, \dots, \mathbf{v}_t^n, \dots, \mathbf{v}_t^q]$, where

$v_t^k \in [0, 1], 1 \leq k \leq K$, and $\mathbf{v}_t^n = [v_t^{(n-1)m+1}, \dots, v_t^{nm}], 1 \leq n \leq q$. The modulator maps each \mathbf{v}_t^n to a complex valued signal $s_t^n = \mu(\mathbf{v}_t^n)$ chosen from a 2^m -ary constellation χ according to the labeling map μ . The space-time block encoder takes the q constellation signals (s_t^1, \dots, s_t^q) to form an $L \times N_t$ space-time code word matrix $\mathbf{X}_t = [\mathbf{x}_t^i]$, where N_t is the number of the transmit antennas, and L is the number of the time slots for transmitting one space-time code word, and $x_t^i, 1 \leq i \leq N_t, 1 \leq l \leq L$ is the transmitted signal from the i -th antenna at time l .

Let χ be the set of space-time code word matrices. The modulator (μ, χ) and the STBC \mathcal{G} jointly define the overall one-to-one mapping rule $\mathcal{M} : [0, 1]^K \rightarrow \chi$. $\forall \mathbf{X} \in \chi$, we denote the corresponding K -tuple binary label as $\mathcal{M}^{-1}(\mathbf{X})$. Note that, for a fair comparison, we fix the total radiated power $E_s = 1$ independent of N_t . Define the rate of the STBC as $R_{ST} = q/L$ (Tarokh et al. 1999a). Thus the overall information rate of the system is $R = mR_cR_{ST}$, and the average energy per information bit is $E_b = E_s/R = 1/R$.

Consider the receiver that is equipped with N_r receive antennas. The received signal is represented by an $L \times N_r$ matrix $\mathbf{Y}_t = [\mathbf{y}_t^j]$, where $y_t^j, 1 \leq j \leq N_r, 1 \leq l \leq L$ is the received signal by the j -th receive antenna at time l .

The channel is described by an $N_t \times N_r$ matrix $\mathbf{H}_t = [h_{i,j}]$, where $h_{i,j}, 1 \leq i \leq N_t, 1 \leq j \leq N_r$ is the path gain from transmit antenna i to receive antenna j . For Rayleigh fading channels, the coefficients $h_{i,j}$ are modeled as independent and identically distributed (i.i.d.) complex Gaussian random variables (RVs) with zero mean and variance 0.5 per dimension. For fast-fading MIMO channels, we assume that \mathbf{H}_t remains constant during the transmission of one single code word \mathbf{X}_t , and varies to new independent realizations in every L symbol period. This fast-fading channel model is an accurate representation of BI-STCM with sufficient interleaving depth.

The $L \times N_r$ received signal is given by

$$\mathbf{Y}_t = \mathbf{X}_t \mathbf{H}_t + \mathbf{W}_t \quad (15)$$

where \mathbf{W}_t is an $L \times N_r$ noise matrix whose entries are modeled as i.i.d. complex Gaussian RVs with zero mean and variance $N_0/2$ per dimension.

The BI-STCM receiver is shown in Figure 11(b). We assume that the CSI is perfectly known at the receiver.

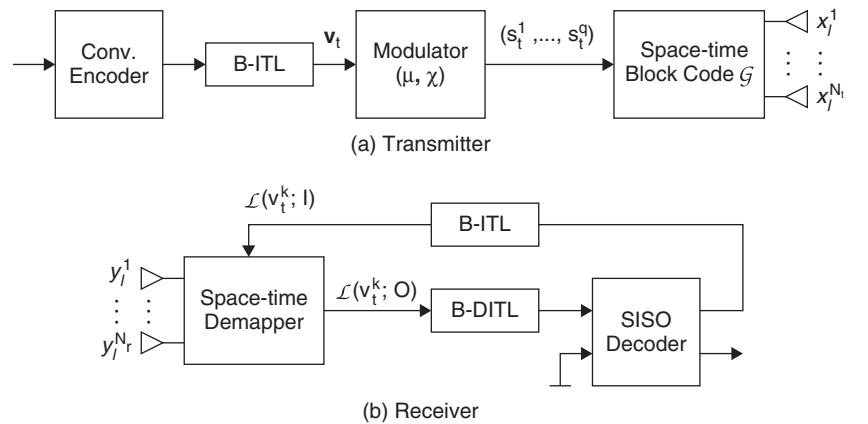

Figure 11: Bit-interleaved space-time coded modulation with iterative decoding

The metric associated with each received signal \mathbf{Y}_t is the log conditional probability density function (pdf)

$$\Lambda(\mathbf{Y}_t|\mathbf{X}_t) = \log p(\mathbf{Y}_t|\mathbf{X}_t) = N_r L \cdot \log \frac{1}{\pi N_0} - \frac{1}{N_0} \|\mathbf{Y}_t - \mathbf{X}_t \mathbf{H}_t\|^2 \quad (16)$$

The space-time demapper uses the maximum a posteriori (MAP) decoding algorithm, and the extrinsic log-likelihood ratio (LLR) for the unmapped bit v_t^k can be computed as

$$L_e(v_t^k; O) = \log \frac{\sum_{\mathbf{x}_t \in \chi_1^k} \exp\{\Lambda(\mathbf{Y}_t|\mathbf{X}_t) + \sum_{\substack{k'=1 \\ k' \neq k}}^K \tilde{v}_t^{k'}(\mathbf{X}_t) L(v_t^{k'}; I)\}}{\sum_{\mathbf{x}_t \in \chi_0^k} \exp\{\Lambda(\mathbf{Y}_t|\mathbf{X}_t) + \sum_{\substack{k'=1 \\ k' \neq k}}^K \tilde{v}_t^{k'}(\mathbf{X}_t) L(v_t^{k'}; I)\}} \quad (17)$$

where χ_1^k (or χ_0^k) is the subset of the space-time code χ in which the labels have the binary value 1 (or 0) at the k -th bit position, and $\tilde{v}_t^{k'}(\mathbf{X}_t)$ is the value of the k' -th bit of the label corresponding to \mathbf{X}_t .

The SISO decoder (Benedetto et al. 1997) takes the bit-deinterleaved (B-DITL) version of $\{L_e(v_t^k; O)\}$ to compute the extrinsic LLR of each coded bit, which is fed back to the demapper as the updated a priori information $L(v_t^k; I)$ on the next iteration.

Due to the large coding gain produced by iterative decoding, one is most interested in the asymptotic performance to which the iterative process converges. The most successful analysis of the BER uses the EF bound introduced by Chindapol and Ritcey (2001) for BICM-ID in a single-antenna system. In the work by Huang and Ritcey (2004), the concept of the EF bound is extended to analyze the asymptotic BER of BI-STCM-ID, and the convergence to the bound and the accuracy of the prediction are verified by simulation. The EF bound is computationally efficient and can be applied to any BI-STCM system configuration.

As shown by Caire et al. (1998), the BICM union bound of the probability of bit error is given by

$$P_b \leq \frac{1}{k_c} \sum_{d=d_f}^{\infty} W_t(d) f(d, \mathcal{M}, \chi) \quad (18)$$

where d_f is the minimum Hamming distance of the convolutional code and $W_t(d)$ is the total input weight of error events at Hamming distance d . Note that $f(d, \mathcal{M}, \chi)$ denotes the pairwise error probability (PEP) and depends only on the Hamming distance d , the overall mapping rule \mathcal{M} , and the space-time code χ .

To analyze the asymptotic BER of BI-STCM-ID, the PEP is bounded by

$$f(d, \mathcal{M}, \chi) \leq \frac{1}{2\pi j} \int_{c-j\infty}^{c+j\infty} [\psi_{\text{ef}}(s)]^d \frac{ds}{s} \quad (19)$$

and

$$\psi_{\text{ef}}(s) = \frac{1}{K 2^K} \sum_{k=1}^K \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^k} \Phi_{\Delta(\mathbf{x}, \mathbf{z})}(s). \quad (20)$$

$\Phi_{\Delta(\mathbf{x}, \mathbf{z})}(s)$ is the Laplace transform of the Pdf of the metric difference $\Delta(\mathbf{x}, \mathbf{z})$. Note that \mathbf{x} is the transmitted signal, and, due to the assumption of error-free feedback, $\mathbf{z} = \mathbf{z}(\mathbf{x}, k)$ is the corresponding erroneously decoded signal having the same binary bit values as those of \mathbf{x} except at the k -th bit position.

It is shown by Huang and Ritcey (2004) that

$$\Phi_{\Delta(\mathbf{x}, \mathbf{z})}(s) = \left(\prod_{i=1}^{N_t} \frac{1}{1 - \lambda_i(-s + s^2 N_0)} \right)^{N_r} \quad (21)$$

where $\lambda_i, i = 1, 2, \dots, N_t$ are the eigenvalues of the $N_t \times N_t$ Hermitian matrix $\mathbf{A} = (\mathbf{X} - \mathbf{Z})^* (\mathbf{X} - \mathbf{Z})$ counting multiplicities.

With equation 21 and equation 20, we apply the Gauss-Chebyshev quadrature (Caire et al. 1998) to compute the PEP (equation 19) and hence the EF bound (equation 18) for BI-STCM-ID. Note that the summation in (equation 18) is truncated at 20 terms, which are enough to ensure the computation accuracy.

As an example, we consider a BI-STCM system equipped with $N_t = 2$ transmit antennas and $N_r = 1$ or 2 receive antennas. We use the best four-state rate 1/2 convolutional code, the 16-QAM MSP labeling (Chindapol and Ritcey 2001), and the Alamouti's space-time block code (Tarokh et al. 1999b).

Figure 12 and Figure 13 compare the simulated BER performance with the EF bounds when 1 and 2 receive antennas are used, respectively. There are ten decoding iterations performed. Each data block contains 10^4 information bits, and a total number of 5×10^8 information bits are simulated for each value of E_b/N_0 considered. The simulation results converge to the EF bounds at low BER. The theoretical EF bounds for BI-STCM-ID are very tight and accurate enough to predict the asymptotic BER performance.

Figure 12: Comparison of the simulated BER performance with the EF bound for a BI-STCM system with two transmit antennas and one receive antenna; 16-QAM MSP labeling, four-state rate 1/2 convolutional code, and Alamouti's space-time block code

Figure 13: Comparison of the simulated BER performance with the EF bound for a BI-STCM system with two transmit antennas and two receive antennas; 16-QAM MSP labeling, four-state rate 1/2 convolutional code, and Alamouti's space-time block code

Note that computing the EF bound is much easier than the intensive BER simulation of the whole system. Also, the analytical bound is very general and can be applied for any BI-STCM configuration: convolutional (or turbo) code, constellation labeling map, and space-time block code.

Now, we consider the design of BI-STCM-ID over fast Rayleigh fading MIMO channels with N_t transmit and N_r receive antennas. The design criterion is to achieve the largest asymptotic coding gain inherited in the constellation labeling. In particular, for orthogonal STBCs designed by Tarokh et al. (1999b), the labeling design criterion reduces to maximizing the $(-N_t N_r)$ -th power mean of the complete set of squared Euclidean distances associated with all error-free feedback events in the constellation (Huang and Ritcey 2005b). This power mean criterion for orthogonal STBCs can be viewed as the generalized version of the harmonic mean criterion (Caire et al. 1998) for BICM-ID in single-antenna systems.

For conventional BICM-ID, good labeling maps were proposed by Chindapol and Ritcey (2001) for 16-QAM and by Li et al. (2002) for 8-PSK constellation. These results were obtained through random computer search; recently, the binary switching algorithm has been applied to solve this labeling optimization problem (Schreckenbach et al. 2003). Basically, all these labeling maps are designed only for single-antenna systems and thus do not necessarily hold their performance in MIMO channels. For BI-STCM-ID, the effects of different labelings were studied by Zhao, Lampe, and Huber (2003). However, the labelings therein are only based on hand-crafted design, and their optimality (in the sense of asymptotic coding gain) is not guaranteed. On the other hand, adaptive labeling was proposed by Samra, Ding, and Hahn (2003) to exploit the diversity gain from multiple packet transmissions, in which the optimal schemes were obtained by solving a well-known QAP (see Cela [1998] and references therein).

For BI-STCM-ID, based on the power mean criterion, it is shown by Huang and Ritcey (2005b) that the labeling

optimization problem for BI-STCM-ID also falls into the category of a QAP, and can be conveniently solved via the generic solutions to the QAP for constellations of any shape and with an arbitrary number of transmit and receive antennas. For a set of practical values of N_t and N_r , we present the optimal labeling maps for 8-PSK, 16-QAM, and 64-QAM constellations along with the maximum asymptotic coding gains.

Recalling the BICM union bound of the probability of bit error (Caire et al. 1998)

$$P_b \leq \frac{1}{k_c} \sum_{d=d_f}^{\infty} W_l(d) f(d, \mathcal{M}, \chi). \quad (22)$$

For BI-STCM, the union bound of the PEP $f(d, \mathcal{M}, \chi)$ can be upper-bounded using the Chernoff technique (Hong and Hughes 2001)

$$f_{ub}(d, \mathcal{M}, \chi) \leq \left[\frac{1}{K 2^K} \sum_{k=1}^K \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^k} \sum_{\mathbf{z} \in \chi_b^{\bar{k}}} \min_s \Phi_{\Delta(\mathbf{x}, \mathbf{z})}(s) \right]^d \quad (23)$$

where \mathbf{X} and \mathbf{Z} are the transmitted and erroneously decoded signals, respectively, and \bar{b} is the complement of b . Here $\Phi_{\Delta(\mathbf{x}, \mathbf{z})}(s)$ is the Laplace transform of the pdf of the metric difference $\Delta(\mathbf{X}, \mathbf{Z}) = \|\mathbf{Y} - \mathbf{Z}\mathbf{H}\|^2 - \|\mathbf{Y} - \mathbf{X}\mathbf{H}\|^2$. It is shown by Tarokh et al. (1998) that

$$\min_s \Phi_{\Delta(\mathbf{x}, \mathbf{z})}(s) = \left[\prod_{i=1}^r \left(1 + \frac{\lambda_i}{4N_0} \right) \right]^{-N_r} \quad (24)$$

where λ_i are the nonzero eigenvalues of the matrix $\mathbf{A} = (\mathbf{X} - \mathbf{Z})^*(\mathbf{X} - \mathbf{Z})$, and r is the rank of \mathbf{A} .

We focus on the asymptotic performance of BI-STCM-ID (i.e., the BER floor to which the iterative decoding process converges). In such cases, irrelevant error items in equation 23 can be effectively expurgated to approach the error-free feedback performance (Huang and Ritcey 2004)

$$f_{ef}(d, \mathcal{M}, \chi) \leq \left[\frac{1}{K 2^K} \sum_{k=1}^K \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^k} \min_s \Phi_{\Delta(\mathbf{x}, \tilde{\mathbf{z}})}(s) \right]^d \quad (25)$$

where the labels $\mathcal{M}^{-1}(\mathbf{X})$ and $\mathcal{M}^{-1}(\tilde{\mathbf{Z}})$ differ only in the k -th bit position. As $N_0 \rightarrow 0$, using equation 24 and equation 25, we find

$$\begin{aligned} f_{ef}(d, \mathcal{M}, \chi) &\sim \left[\frac{1}{K 2^K} \sum_{k=1}^K \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^k} \left(\prod_{i=1}^{\tilde{r}} \frac{\tilde{\lambda}_i}{4N_0} \right)^{-N_r} \right]^d \\ &= \left[\frac{4}{\Omega^2/N_0} \right]^{\tilde{r} N_r d} \end{aligned} \quad (26)$$

where we define

$$\Omega^2(\chi, \mathcal{M}, N_r) = \left[\frac{1}{K 2^K} \sum_{k=1}^K \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^k} \left(\prod_{i=1}^{\tilde{r}} \tilde{\lambda}_i \right)^{-N_r} \right]^{1/(\tilde{r} N_r)} \quad (27)$$

and $\tilde{\lambda}_i$ are the nonzero eigenvalues of the matrix $\tilde{\mathbf{A}} = (\mathbf{X} - \tilde{\mathbf{Z}})^*(\mathbf{X} - \tilde{\mathbf{Z}})$, and \tilde{r} is the rank of $\tilde{\mathbf{A}}$. Using

equation 26 and only including the dominant error event associated with d_f in (22) as $N_0 \rightarrow 0$, we can write

$$P_b \approx \frac{1}{k_c} W_I(d_f) f_{\text{ef}}(d_f, \mathcal{M}, \chi) = \frac{1}{k_c} W_I(d_f) \left[\frac{4}{\Omega^2 / N_0} \right]^{\tilde{r} N_r d_f} \quad (28)$$

Recalling the definition of the overall information rate R and $E_b = 1/R$, the asymptotic BER performance of BI-STCM-ID can be represented as

$$\log_{10} P_b \approx -\frac{\tilde{r} N_r d_f}{10} \left[(R\Omega^2)_{\text{dB}} + \left(\frac{E_b}{N_0} \right)_{\text{dB}} \right] + \text{const}, \quad (29)$$

which is similar to that of conventional BICM derived by Caire et al. (1998). Thus, for large values of E_b/N_0 , the BER curve on a logarithmic scale approximates a straight line with slope proportional to the overall diversity order $\tilde{r} N_r d_f$, shifted horizontally by the offset $(R\Omega^2)_{\text{dB}}$. Apparently, to achieve the best BER performance, full-diversity STBCs should be used to obtain the largest diversity gain $N_t N_r d_f$; for maximizing the coding gain Ω^2 , as we will show next, constellation labeling optimization is involved.

To maximize the coding gain Ω^2 defined in equation 27 optimization of the overall mapping rule \mathcal{M} is required. We focus on orthogonal STBCs, which offer full transmit diversity and the advantage of low-complexity linear processing in the decoding scheme (Tarokh et al. 1999a). For orthogonal STBCs, we will see that this optimization problem reduces to the constellation labeling design.

Definition 1 For any constellation χ with labeling map μ , the $(-p)$ -th error-free feedback power mean is

$$\omega^2(\chi, \mu, p) = \left[\frac{1}{m 2^m} \sum_{k=1}^m \sum_{b=0}^1 \sum_{s \in \chi_b^k} (|s - \tilde{s}|^2)^{-p} \right]^{\frac{1}{p}} \quad (30)$$

where the labels $\mu^{-1}(s)$ and $\mu^{-1}(\tilde{s})$ differ only in the k -th bit position.

Theorem 1 (The Power Mean Criterion for Orthogonal STBCs) For any generalized orthogonal design \mathcal{G} in variables $\pm s_1, \pm s_1^*, \pm s_2, \pm s_2^*, \dots, \pm s_q, \pm s_q^*$, that satisfies

$$\mathcal{G}^* \mathcal{G} = \alpha \left(\sum_{n=1}^q |s_n|^2 \right) \mathbf{I}_N \quad (31)$$

$$\max_{\mathcal{M}} \Omega^2(\chi, \mathcal{M}, N_r) = \alpha \max_{\mu} \omega^2(\chi, \mu, N_t N_r).$$

Proof: First, consider $k = 1, \dots, m$. For any $\mathbf{X} = \mathcal{G}(s_1, s_2, \dots, s_q)$, recalling the definition of $\tilde{\mathbf{Z}}$ and \tilde{s} , we have $\tilde{\mathbf{Z}} = \mathcal{G}(\tilde{s}_1, \tilde{s}_2, \dots, \tilde{s}_q)$. Thus $(\mathbf{X} - \tilde{\mathbf{Z}}) = \mathcal{G}(s_1 - \tilde{s}_1, 0, \dots, 0)$, and $(\mathbf{X} - \tilde{\mathbf{Z}})^* (\mathbf{X} - \tilde{\mathbf{Z}}) = \alpha |s_1 - \tilde{s}_1|^2 \mathbf{I}_{N_t}$. Then it follows that

$$\begin{aligned} \Omega^2(\chi, \mathcal{M}, N_r) &= \left[\frac{q}{K 2^K} \sum_{k=1}^m \sum_{b=0}^1 \sum_{\mathbf{x} \in \chi_b^k} (\alpha |s_1 - \tilde{s}_1|^2)^{-N_t N_r} \right]^{\frac{1}{N_t N_r}} \\ &= \left[\frac{q 2^{(q-1)m}}{K 2^K} \sum_{k=1}^m \sum_{b=0}^1 \sum_{s \in \chi_b^k} (\alpha |s - \tilde{s}|^2)^{-N_t N_r} \right]^{\frac{1}{N_t N_r}} \\ &= \alpha \omega^2(\chi, \mu, N_t N_r). \end{aligned}$$

Hence, maximizing the asymptotic coding gain $\Omega^2(\chi, \mathcal{M}, N_r)$ over \mathcal{M} reduces to maximizing the power mean $\omega^2(\chi, \mu, N_t N_r)$ over all labeling maps μ of the constellation.

Remark 1 The power mean criterion for orthogonal STBCs can be viewed as the generalized version of the harmonic mean criterion (Caire et al. 1998) for BICM-ID in single-antenna systems.

Corollary 1 (The Power Mean Criterion for Parallel Transmission) For the “parallel transmission” scheme $\mathcal{G}(s_1, \dots, s_q) = [s_1 \dots s_q]$ (with no space-time coding, e.g., Hochwald and ten Brink [2003]),

$$\max_{\mathcal{M}} \Omega^2(\chi, \mathcal{M}, N_r) = \max_{\mu} \omega^2(\chi, \mu, N_r). \quad (32)$$

Proof: For $k = (n-1)m + 1, \dots, nm$, $1 \leq n \leq q$, $(\mathbf{X} - \tilde{\mathbf{Z}}) = [0 \dots (s_n - \tilde{s}_n) \dots 0]$, and $(\mathbf{X} - \tilde{\mathbf{Z}})^* (\mathbf{X} - \tilde{\mathbf{Z}}) = \text{diag}(0, \dots, |s_n - \tilde{s}_n|^2, \dots, 0)$. The proof immediately follows Theorem 1.

Corollary 2 For BI-STCM-ID with either orthogonal STBCs or parallel transmission, the maximum asymptotic coding gain is a nonincreasing function of the diversity order.

Proof: Consider the BI-STCM-ID system with diversity order p ($p = N_t N_r$ for orthogonal STBCs and $p = N_r$ for parallel transmission). Let $\mu_1 = \arg \max_{\mu} \omega^2(\chi, \mu, p_1)$ and $\mu_2 = \arg \max_{\mu} \omega^2(\chi, \mu, p_2)$. Then, for $p_1 < p_2$, it follows that

$$\omega^2(\chi, \mu_1, p_1) \geq \omega^2(\chi, \mu_2, p_1) \geq \omega^2(\chi, \mu_2, p_2)$$

where the last inequality is the immediate result from the well-known power mean inequality (Bullen 2003).

Remark 2 Corollary 2 reveals the basic trade-off between the spatial diversity gain and the maximum asymptotic coding gain in a BI-STCM-ID system.

When orthogonal STBCs are used for BI-STCM-ID, according to Theorem 1, the optimization problem becomes $\max_{\mu} \omega^2(\chi, \mu, N_t N_r)$. Even for a medium-sized constellation, this becomes a formidable combinatorial optimization problem whose solution space contains $(2^m)!$ items. For example, for 16-QAM, $16! \approx 2.1 \times 10^{13}$, and for 64-QAM, $64! \approx 1.3 \times 10^{89}$. However, as we show next, by careful construction, this problem falls into the category of a classical quadratic assignment problem (QAP; see, e.g., Cela [1998] and references therein), and can be solved conveniently by applying the generic solutions to the QAP.

The QAP is one of the most difficult but extensively studied problems in optimization. We provide the general definition of the QAP (Cela 1998) for the completeness of presentation.

Definition 2 Consider a set $\mathcal{N} = \{1, 2, \dots, n\}$ and two $n \times n$ matrices $\mathbf{F} = (f_{i,j})$ and $\mathbf{D} = (d_{k,l})$. The quadratic assignment problem with coefficient matrices \mathbf{F} and \mathbf{D} , shortly denoted by $\text{QAP}(\mathbf{F}, \mathbf{D})$, can be stated as follows

$$\min_{\pi \in \Pi_{\mathcal{N}}} \sum_{i=1}^n \sum_{j=1}^n f_{i,j} d_{\pi(i), \pi(j)} \quad (33)$$

where $\Pi_{\mathcal{N}}$ is the set of all permutations of \mathcal{N} .

One of the major applications of the QAP is in location theory (Cela 1998), where $f_{i,j}$ is the flow of materials from facility i to facility j , and $d_{k,l}$ is the distance from location k to location l . The objective is to find an assignment of all facilities to all locations (i.e., a permutation $\pi \in \Pi_{\mathcal{N}}$) such that the total cost of the assignment is minimized.

Proposition 1 Maximization of the power mean $\omega^2(\chi, \mu, N_t N_r)$ over all labeling maps μ is a QAP.

Proof: Since $N_t N_r > 0$, $\max_{\mu} \omega^2(\chi, \mu, N_t N_r)$ is equivalent to

$$\min_{\mu} \sum_{k=1}^m \sum_{b=0}^1 \sum_{s \in \chi_b^k} (|s - \tilde{s}|^2)^{-N_t N_r} \quad (34)$$

Using the facility-location analogy, let the constellation points $\{s_k | k = 0, \dots, 2^m - 1\}$ be the locations, and the labels $\{\beta(i) | i = 0, \dots, 2^m - 1\}$ the facilities, where $\beta(i)$ denotes the m -tuple binary label corresponding to integer i . By construction, we define the “distance” (as in Definition 2) between s_k and s_l as

$$d_{k,l} = d_{s_k, s_l} = \begin{cases} (|s_k - s_l|^2)^{-N_t N_r} & k \neq l \\ 0 & k = l \end{cases} \quad (35)$$

and define the “flow” between labels $\beta(i)$ and $\beta(j)$ as

$$f_{i,j} = \begin{cases} 1, & \beta(i) \text{ and } \beta(j) \text{ differ only in one bit position} \\ 0, & \text{otherwise} \end{cases} \quad (36)$$

Thus, equation 34 becomes

$$\min_{\mu} \sum_{i=0}^{2^m-1} \sum_{j=0}^{2^m-1} f_{i,j} d_{\mu(\beta(i)), \mu(\beta(j))}. \quad (37)$$

Since the mapping rule $\mu: s_k = \mu(\beta(i))$ is essentially a permutation (of the indices) $\pi: k = \pi(i)$, equation 37 can be written as

$$\min_{\pi} \sum_{i=0}^{2^m-1} \sum_{j=0}^{2^m-1} f_{i,j} d_{\pi(i), \pi(j)}, \quad (38)$$

which is a QAP as in Definition 2.

Now we show the best labeling maps for 8-PSK, 16-QAM, and 64-QAM constellations. Each labeling map is optimized in order to achieve $\max \omega^2(\chi, \mu, p)$ for a given diversity order p . The values of p under consideration and the corresponding space-time transmission schemes are listed in Table 2.

For 8-PSK constellation, since there are only $8! = 40320$ candidates, the optimal labeling can be obtained by an exhaustive computer search. Figure 14 shows the semiset partitioning (SSP) labeling (Li et al. 2002), which is optimized for conventional BICM-ID. The SSP labeling is found to be the universal optimal labeling for any diversity order p in Table 2. Note that the optimal labeling is not unique, (e.g., any rotated or reflected version of the SSP labeling is also optimal).

Table 2: The Diversity Order p and the Corresponding Space-Time Block Codes.

Diversity Order	Examples of STBCs
$p = 1$	Conventional BICM-ID (single-antenna system)
$p = 2$	Alamouti's G_2 (Tarokh et al. 1999b), 2×1 channel; Parallel transmission (Hochwald and ten Brink 2003), 2×2 channel
$p = 4$	Alamouti's G_2 , 2×2 channel; Parallel transmission, 4×4 channel
$p = 8$	Parallel transmission, 8×8 channel
$p = 9$	G_3 and H_3 (Tarokh et al. 1999a), 3×3 channel
$p = 16$	G_4 and H_4 (Tarokh et al. 1999a), 4×4 channel

For 16-QAM and 64-QAM constellations, the optimal labeling maps can be obtained by applying the reactive tabu search (RTS) algorithm (Battiti and Tecchiolli 1994) for the QAP. In the RTS, an explicit check for the repetition of assignment configurations is performed, and the appropriate size of the list of forbidden moves is automatically determined by reacting to the occurrence of cycles. Moreover, if the search appears to be repeating in an excessive frequency, the search is diversified by a random number of moves that is proportional to the average of the cycle length (Battiti and Tecchiolli 1994).

In the labeling map search, for each diversity order considered, the RTS algorithm (Battiti and Tecchiolli 1994) performs thirty trials, each with 10^5 iterations, which are sufficiently large to guarantee convergence to the optimal results. The run time (on a Sun Ultra-10 workstation) with such a configuration is less than six minutes for 16-QAM and only about one and a half hours for 64-QAM. Table 3 lists the optimal labeling results (with the labels in decimal format) for 16-QAM. The constellation points are labeled (A, B, ..., P) from left to right and from top to bottom (see Figure 15). Table 4 through Table 6 list the optimal labeling maps for 64-QAM for the diversity order $p = 1, 2, 4$. The labels are arranged row by row, showing their locations in the constellation.

In Table 7, we compare the asymptotic coding gain for 16-QAM with Gray labeling, MSP labeling (Chindapol

and Ritcey 2001), and the labeling maps optimized for each specific value of p . As expected, the Gray labeling yields the smallest asymptotic coding gain for all cases. The MSP labeling, which is designed for BICM-ID in single-antenna systems, quickly loses its large coding gain as the diversity order p increases. The optimal labeling maps are about 7 dB superior to Gray labeling and 3 dB to the MSP labeling for $p > 4$. For 64-QAM constellation, Table 8 shows even more significant gains (around 13 dB) achieved by the optimal labeling maps over Gray labeling. As seen from both tables, the optimal asymptotic coding gain decreases as the diversity order p increases, which confirms Corollary 2.

16	21	50	28	2	61	56	49

*The labels are in decimal format (e.g., 11 = 001011₂).

It is well known that constellation labeling has significant impact on decoder convergence of BICM-ID, and this is clearly illustrated by the extrinsic information transfer (EXIT) chart (ten Brink 2000). Similarly, we can apply the EXIT chart technique to investigate the convergence behavior of different labeling maps for BI-STCM-ID. As an

Table 7: Comparison of the Asymptotic Coding Gain $\omega^2(\chi, \mu, p)$ for 16-QAM with Different Labeling Maps

	Gray	MSP	Optimal	Gain over Gray (dB)	Gain over MSP (dB)
$p = 1$	0.5143	2.2780	2.7190	7.2319	0.7686
$p = 2$	0.4609	1.9438	2.5460	7.4225	1.1721
$p = 4$	0.4298	1.4921	2.3414	7.3621	1.9568
$p = 8$	0.4147	1.1288	2.1791	7.2054	2.8566
$p = 9$	0.4130	1.0874	2.1591	7.1832	2.9788
$p = 16$	0.4073	0.9512	1.8418	6.5533	2.8697

$p = 1$	0.1546	2.8742	12.6931
$p = 2$	0.1243	2.7236	13.4067
$p = 4$	0.1090	2.4903	13.5883

**Figure 16:** Comparison of space-time demapper transfer functions with 16-QAM Gray labeling, MSP labeling, and $p=2$ optimal and proposed labeling; Alamouti's space-time block code, 2×1 fast Rayleigh fading channels.

example, Figure 16 shows the EXIT chart of a BI-STCM-ID system that uses a four-state rate 1/2 convolutional code, 16-QAM modulation, and the Alamouti's STBC (Tarokh et al. 1999b) over a 2×1 channel at $E_b/N_0 = 4.3$ dB. We compare space-time demapper transfer functions for several labelings: Gray, MSP, and the one optimized

for $p=2$. As seen from the EXIT chart, when there is perfect a priori information, the transfer function of the optimal labeling achieves the largest value, indicating its optimality in the sense of the lowest asymptotic BER floor. When there is little a priori information, the optimal labeling has the lowest transfer function, which implies a larger *pinch-off* limit (ten Brink 2000) in SNR to achieve decoder convergence. Similar results can be found in Figure 17, in which the Alamouti's STBC is used over a 2×2 channel at $E_b/N_0 = 1.0$ dB.

To obtain the constellation labeling with large asymptotic coding gain and good convergence property, we use the RTS software to produce a list of candidate labeling maps, ordered by the asymptotic coding gain $\omega^2(\chi, \mu, p)$. We examine the space-time demapper transfer functions for several top labeling maps, and select the one with the fastest convergence. As an example, Figure 18 (a) and Figure 18(b) show the recently proposed 16-QAM

**Figure 17:** Comparison of space-time demapper transfer functions with 16-QAM Gray labeling, MSP labeling, and $p=4$ optimal and proposed labeling; Alamouti's space-time block code, 2×2 fast Rayleigh fading channels

Figure 18: Recently proposed 16-QAM constellation labeling maps with improved convergence property for the BI-STCM system with the Alamouti scheme and (a) $N_r = 1$ or (b) $N_r = 2$ receive antennas

labeling maps (Huang and Ritcey 2005a) for the Alamouti's scheme with one and two receive antennas, respectively. Their improved convergence property can be clearly observed in Figure 16 and Figure 17 with higher demapper transfer functions (the star-marked dashed curves) than those of the optimal labelings in the low a priori information region. On the other hand, the asymptotic coding gains achieved by the two proposed labeling maps have negligible differences (less than 0.1 dB) from those optimized for $p = 2$ and $p = 4$ in Table 3.

Figure 19 compares the simulated BER performance for the proposed labeling maps and the 16-QAM MSP labeling with one or two receive antennas. Fifteen decoding iterations are performed. Each data block contains 10^5 information bits and 5×10^8 information bits are simulated for each value of E_b/N_0 considered. For both $N_r = 1$ and $N_r = 2$, the proposed labeling maps outperform the MSP labeling by about 1 dB coding gain around the

BER of 10^{-6} . The tight EF bounds developed by Huang and Ritcey (2004) are also shown for reference.

CONCLUSION

In this chapter, we present a comprehensive review of recent research developments on bit-interleaved coded modulation over fading channels that represent the majority of those used for wireless data networks. After a short introduction to digital communications over fading channels, we addressed an important subclass of coded modulations—BICM. For a single-antenna communications system, we present design principles for BICM and BICM with iterative decoding. Regarding the more practical issues in the real system design, we discussed the impact of imperfect channel state information on the performance of BICM-ID, and reviewed recently proposed algorithms for joint iterative channel estimation and decoding. Imperfect channel knowledge is a critical aspect for real-world channels. For multiple-antenna communications systems, we present recent research on bit-interleaved space-time coded modulation with iterative decoding. This extends conventional BICM-ID to multiple-input multiple-output systems. MIMO is used in many wireless systems, and can currently be found even in inexpensive 802.11 home network products. We introduce a very tight theoretical bound to accurately predict the asymptotic bit error rate. Based on the asymptotic BER analysis, a design criterion is developed to achieve the largest asymptotic coding gain inherited from the underlying constellation labeling. BI-STCM-ID is considered a promising candidate for the next generation high-data-rate, high-performance wireless networks. BICM remains an important antecedent for many modern coded modulations. We expect to see its impact on many future generation wireless systems.

GLOSSARY

Asymptotic Bounds: The use of large signal-to-noise ratio (SNR) approximations to simplify or upper-bound a mathematical expression.

Bandwidth: A measure of frequency spread required for transmission. This is usually set by a regulatory authority, such as the FCC in the United States.

Bit Error Rate: The fraction of bits that one expects to erroneously decode. For digital communication systems to be useful, this must be extremely small—roughly one part in a million, or less.

Bit Interleaving: The system component that pseudo-randomly reorders the coded data bits for transmission. A complementary bit deinterleaver is used at the receiver.

Channel Capacity: A limit or bound on the amount of information that can be sent across a channel with negligibly small bit error rate. Generally, this increases with SNR and bandwidth.

Channel State Information: Auxiliary information about the channel, beyond the values of the transmitted bit stream. Typically this includes the carrier frequency and phase, time of arrival, and amplitude levels in a fading channel.

Coded Modulation: A digital communication system that encodes a bit stream using a convolutional, block, or other channel encoder and maps groups of bits to channel symbols.

Coherent Digital Communications: A digital communication system is coherent if it is modulated onto a frequency carrier in such a way that the frequency and phase of the carrier remain stable over the transmission. This is the standard high-performance approach to modern communication systems over channels that do not change radically over a time period much longer than the inverse of the bandwidth. In other words, the receiver must be able to carry out frequency and phase estimation.

Constellation Labeling: In a coherent modulation, a constellation of transmitted symbols is used. Each symbol must be labeled with the group of bits that selects the symbol value. For example, four bits can select one of $2^4 = 16$ symbols.

Data Rate: The rate, in bits per second, of transmitting information across the channel. One must distinguish between the bit rate and the symbol, or baud, rate by the choice of units of information.

Detection: Signal processing at the receiver to detect or decode the unknown values of the transmitted symbols. Because these symbols are drawn from a discrete finite alphabet, there is only a finite number of possible symbol values. This is in contrast to analog communications in which the transmitted waveform can take on an infinite number of values. Because of this fundamental fact, detection is easier than estimation.

Digital Communications: A communication system that transmits discrete levels, or bits of information, in contrast to continuous or analog levels.

Diversity: A measure of the number of statistically independent looks at the channel. Diversity can be increased through encoding information so that each

bit is effectively transmitted over many different and independent channel realizations. It can be obtained as temporal diversity, spatial diversity, and frequency diversity, among others, and depends heavily on the particular application.

Estimation: Signal processing at the receiver to estimate the unknown values of the channel state information, such as the fading amplitude and phase. This requires either sounding the channel with pilot symbols of known value, or iterative estimation and decoding.

Fading Channel: A communication channel that introduces amplitude and phase variations along with additive Gaussian noise.

Gaussian Noise: The ever-present noise in any electronic system due to the thermal motion of electrons in resistors. It is also a good model of other external noise sources outside of the receiver.

Iterative Decoding: A decoding process that makes multiple passes over the data, utilizing constraints among bits introduced by the channel coding to aid the detection of unknown bit values. Bits that can be easily decoded, due to random chance, are used to aid the decoding of other bits that are related through the constraints. Given sufficient SNR to bootstrap this process, iteration can be used to reach a very low level of resultant bit errors.

Orthogonal Frequency Division Multiplexing (OFDM): A recent digital-signal-processing based communication system in which the channel bandwidth is partitioned into orthogonal sub-carriers, each with its own transmission. The advantage stems from transformation of frequency-selective to flat or frequency-nonselective fading, which is more easily handled at the receiver. OFDM will be widely deployed in WiMAX and fourth generation (4G) cellular systems.

Signal-to-noise Ratio: A fundamental metric that describes the channel conditions. In digital communications, this is actually an energy ratio E_b/N_o at the detector. In signal processing, a power ratio S/N at the system input is often implied. These can be related through the data rate and bandwidth:

$$\frac{S}{N} = \frac{E_b}{N_o} \frac{R_b}{W}$$

Space-time Coding: A coded modulation system that uses multiple antenna elements at the transmitter in conjunction with multi-symbol modulation to increase the diversity at the receiver. This is very important for handheld receivers for which multiple receive antennas are impractical.

Trellis-coded Modulation: A coded modulation communication system with a jointly designed convolutional encoder followed by a memoryless mapper for a higher-order constellation. One advantage is that the bandwidth expansion, normally introduced by the encoder redundancy, is eliminated.

INTRODUCTION

The Wireless Application Protocol (WAP) is a set of standards or protocols that help bring the contents of the Internet to a mobile device. Before WAP was introduced, the users of mobile devices had very limited interactive data services. A variety of interactive services including emailing by mobile device, stock market quotes, news headlines, etc. are now available thanks to WAP.

This chapter presents the essential WAP concepts. It contains a description of the WAP2.0 specification which offers greater flexibility by accommodating better bandwidth, quick data speeds, and improved technology. The chapter can act both as a resource for developers and an introductory guide to a reader who is new to WAP.

After a brief history of WAP, the chapter is broadly divided into four sections: the overall architecture specification of WAP with details of the associated technologies including the security aspect; a description of some WAP applications and the architectures involved; an introduction to XHTMLMP—a scripting language for scripting WAP applications; and the design considerations needed when developing WAP applications. The chapter concludes with a summary and look ahead to where WAP may be heading.

A Brief History of WAP

The Wireless Application Protocol is a global standard for getting Internet content to mobile devices. In the 1990s several vendors were working on the mobile Internet and, as a result, several technologies emerged. Some of the popular ones include Nokia's Narrow Band Sockets (NBS) and Tagged Text Markup Language (TTML), Ericsson's Intelligent Terminal Transfer Protocol (ITTP), and Unwired Planets Handheld Device Markup Language (HDML). Each technology had its own purpose and some overlapped. This led to the fragmentation of the industry based on the providers. The WAP Forum was founded to aid communication among the various organizations and to provide a common set of protocols and technologies.

The WAP standards are regulated by this consortium (WAP Forum), which is now consolidated with the Open Mobile Alliance. Founded by Ericsson, Motorola, Nokia, and Open Wave in June 1997, the Open Mobile Alliance includes numerous members who are the service and content providers. An important goal of the WAP Forum is to ensure that access to the Internet by cell phones is not limited by the underlying network. WAP addresses problems like device limitations, protocol mismatch, and usability.

The Wireless Application Protocol

The Wireless Application Protocol (WAP) is a collection of protocol standards whose purpose is to enable communication between handheld wireless devices and Internet-based service providers. These service providers include Web servers providing general Web content formatted especially for small wireless devices and other service providers who target wireless devices exclusively. WAP brings the content from the Internet and other digital services to wireless handheld terminals.

The original technology built for the Internet was meant for desktops and larger computers. The advent of smaller handheld devices places constraints on the system infrastructure and design paradigms. Compared to desktop or portable computers, the particular limitations of handheld wireless devices include greatly restricted bandwidth, nonrobust connections, signal security limitations, small screens on most devices, limited battery life, restricted input options, more latency, and processor power and memory constraints (WAP Architecture 2001).

In addition to delivering Web content, WAP also provides useful services like personalization of data delivered and options for secure transmission. WAP provides a flexible security infrastructure for communications between a server and client.

The WAP layered architecture is extensible and it enables other services and applications to access the features of the protocols through a set of interfaces. Some popular applications include electronic mail, calendar,

phone book, notepad and electronic commerce related applications.

The WAP Model of Web Content Access

The basic World Wide Web (WWW) model has applications and formatted data residing on a server as illustrated in Figure 1. The contents or the data can be browsed using a Web browser. A URL or the address location of the data is specified to the browser resulting in the data being displayed. The Web browser is an example of a networked application. The browser sends a request to a particular object on the server and the server responds by encoding the contents according to the standard data formats. All the content on the server is named using the standard Uniform Resource Locator (URL). The Hyper Text Transport Protocol (HTTP) is a network protocol that defines communication between a client and Web server on the Internet (WAP Architecture 2001). This is the *pull* model of WWW service interaction, so called because it is initiated by the client device which pulls the data from the server.

As shown in Figure 2, the WAP model also works on this request-response mechanism. Content stored on the Web server can be pulled by the WAP device using a WAP browser. The WAP browser on the WAP device requests for a resource using a URL. The response sent by the HTTP server is the requested content. A popular service provided by WAP is the *push* service. A push initiator on the application server can push the content to a WAP device. The contents are transmitted using the protocols of the web. The browser on the hand held devices is similar

Figure 1: World Wide Web programming model (WAP Architecture 2001)

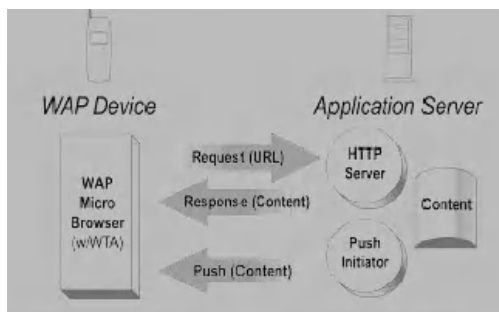

Figure 2: WAP programming model (WAP Architecture 2001)

to a standard Web browser used for browsing the Internet on desktops. Both the push and the pull mechanism can be housed on the same application server as shown in Figure 2 (WAP Architecture 2001).

Figure 2 shows the close relationship between the interactions of a WAP device and an ordinary client in interacting with an application server. The base WWW model is extended in the significant use of the push interaction. Thus the two technologies are very closely related and interdependent.

Performance-Enhancing Proxies

Because information organized for regular Web clients may not be well suited to handheld wireless devices, an additional component is used to bridge the gap in expectations between the Web server and its clients. Figure 3 shows the insertion of a proxy to translate between the features expected by the application server and those available on the WAP-enabled device. Proxies speed up and optimize the connection between the wireless domain and the Web. A Protocol Gateway translates the request from the wireless device to the Web. Content encoders and decoders convert the WAP content to a format that the underlying architecture can use efficiently. An advantage of having proxies is that applications can be developed on standard Web servers using proven Web technologies. Because the proxy performs the conversion between the Web and WAP formats, the existing content on a Web server can be retained. Another advantage of a proxy is that it efficiently uses the limited bandwidth between the handheld devices and the Webserver.

Standards

WAP must deal with two sets of constraints: limitations of wireless data networks and limitations of the handheld devices used to send and receive data. WAP has been designed with these restrictions in mind. Compared with wired or stationary wireless networks, network support for mobile devices include the following constraints:

- less bandwidth,
- more latency,
- less connection stability, and
- inconsistent availability.

Compared with a full featured computer, the format of the typical handheld device adds the following constraints:

- less powerful CPU,
- less memory (ROM and RAM),
- restricted power consumption,
- smaller displays,
- limited input devices.

General network architecture is often described with the International Organization for Standardization (ISO) Open Systems Interconnection (OSI) Reference Model. As seen in Figure 4, the WAP protocol stack is similar to this familiar model.

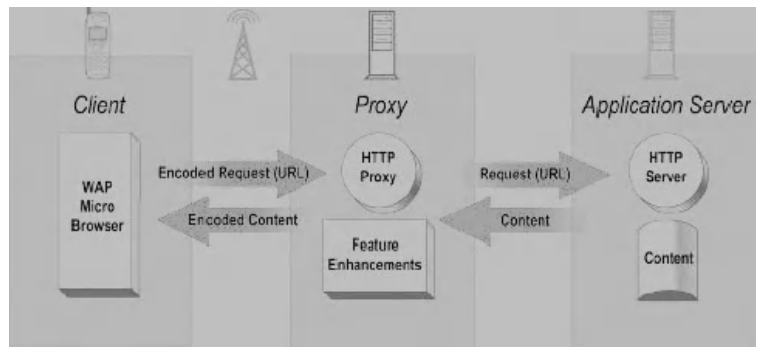

Figure 3: Performance enhancing proxy (WAP Architecture 2001)

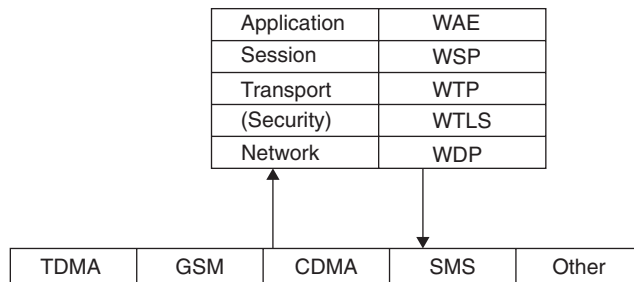

Figure 4: WAP STACK for WAP2.0

Architecture

The WAP architecture is designed to minimize bandwidth consumption. As a result, WAP can work on both low bandwidth and broadband networks. Thus, WAP can operate over networks such as time-division multiple access (TDMA) global system for mobile communications (GSM), code division multiple access (CDMA), and short messaging service (SMS). As shown in Figure 5, the layers of the WAP stack include Wireless Application Environment (WAE), the WAP Session Protocol (WSP), the Wireless Transaction Protocol (WTP), the wireless transport layer security (WTLS) (for which there is no corresponding OSI reference layer), and WAP Datagram Protocol (WDP). A brief summary for each layer in the stack follows:

Wireless Application Environment: The WAE consists of the Wireless Markup Language (WML), XHTML Mobile Profile (XHTMLMP), and WMLScript. A detailed explanation of the WAE follows.

WAP Session Protocol: The WSP is a layer meant for the efficient exchange of data between the applications. A WSP session performs a series of request/response actions with the WTP Layer.

WAP Transaction Protocol: WTP is a layer that provides Transaction services. A sequence of request/response transactions supports both reliable and unreliable datagram deliverance.

Wireless Transport Layer Security: The WTLS is analogous to the HTTPS protocol of the Internet which provides an internet security layer. The WTLS provides the transmission of data using encryption.

WAP Datagram Protocol: The network layer is represented by this protocol in WAP. This layer is accountable for interfacing with the bearer networks like TDMA, GSM, CDMA, SMS, and the smooth transmission of data.

Comparing WAP with Internet Protocols

Using the wired environment, applications can be built using strategies like HTML, scripting languages, and SSL for secure data transport. The WAP standards are completely different from the Internet protocols. The WAP

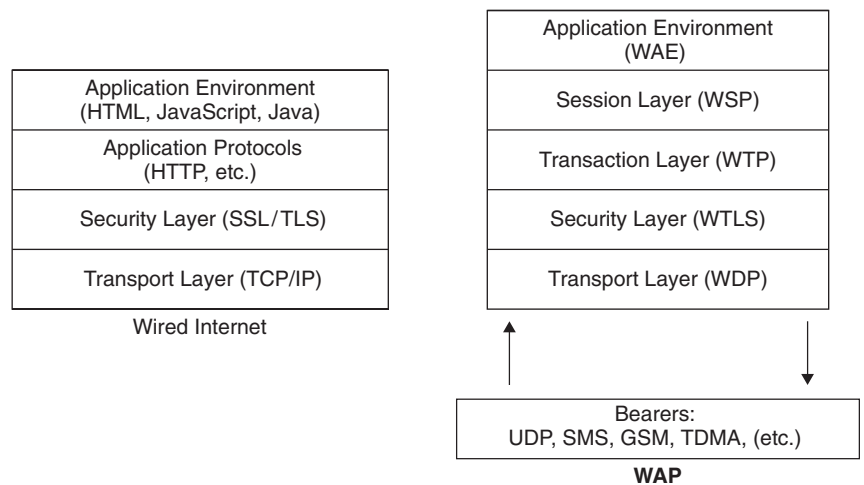

Figure 5: Wired and WAP architectures

protocols are different, the way the data is delivered is different, and the content and scripting languages are also different. The only point where both the standards meet are the security models, which also have minute differences.

Wireless Application Environment

The Wireless Application Environment (WAE) is a framework for the development of applications that can be accessed from many types of wireless devices from a variety of manufacturers. The goal is a structure in which the operators and service providers can build their products with confidence. The framework also uses other WAP technologies including the Wireless Transaction Protocol (WTP) and other Internet related technologies such as XML, URLs, scripting, and various media types. This helps the developers to build applications in a fast and flexible manner. The WAE specification is extensible in the sense that it can accommodate new technologies as they are developed. A study of WAE can be very useful for the developers.

Figure 6 is a Unified Modeling Language (UML) class diagram, which describes each component in the Wireless Application Environment structure in terms of a class. Each box represents one component, with the

class name in the first compartment and the attributes in the second compartment of the box. The Wireless Markup Language (WML) script has the class libraries, which are indicated by the diamond suggesting a whole/part relationship. All the WML entities are associated with the WML2 specification, which in turn is associated with XHTML MP, the current markup language for WAP.

WAE Components

The components of WAE include XHTML Mobile Profile [XHTMLMP], WML, WCSS, WMLScript, WBXML, vCARD, and vCalendar, briefly described below:

XHTML Mobile Profile: W3C's HTML [HTML4] has evolved into XHTML and has been modularized [XHTMLMod], thus allowing operators or service providers to build their applications based on the modules necessary for the target platforms or users.

WML: The wireless markup language, an XML-based markup language designed for use on devices characterized by low bandwidth connections, limited memory and restricted CPU capacity, small screen, and limited user input interfaces.

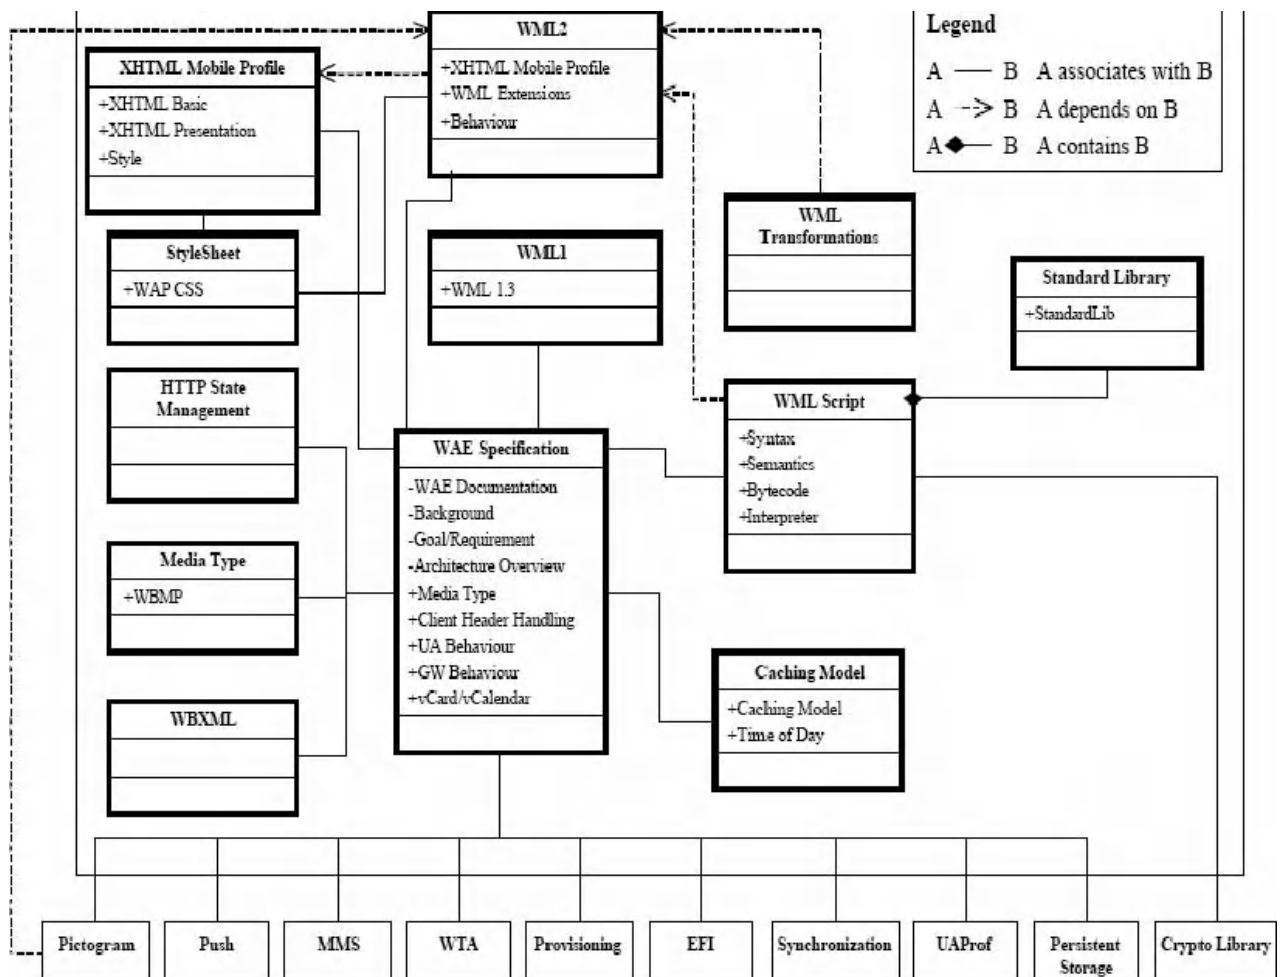

Figure 6: Wireless Application Environment 2 structure (Wireless Application Protocol 2002)

WCSS: Wireless cascading sheets are used in Web development to control display without sacrificing device-independence. WCSS is specified for the features of small mobile devices.

WMLScript: WMLScript is a lightweight scripting language similar to JavaScript, designed to run on small mobile devices.

WBXML: A compact binary representation of XML documents intended to reduce the size of the files for transmission without losing semantic information.

VCard and vCalendar: Industry standards for sharing address and calendar information.

Push and Pull Information Delivery

The normal client server model has a client requesting a service from the server. The server responds by sending the requested data back to the client. This can be thought of as the client pulling data from the server and is called pull technology. In contrast, push technology requires no explicit request from the client. In pull technology, the client initiates the transfer and the server responds. In push technology, the server initiates the transfer and the client accepts the unsought information. Figure 4 summarizes the interaction.

In WAP, a Push Initiator (PI) carries out the push operation by transmitting the content to a Push Proxy Gateway (PPG). The PPG in turn transmits the data to the WAP client. Figure 7 diagrams the components of the Push Framework. The PI is resident on an ordinary Web server. It communicates with the PPG using the Push Access Protocol (PAP). The PPG communicates with the WAP client using the Push Over the Air (OTA) Protocol. (WAP Push Architectural Overview 2001)

The PPG acts between the network of mobile devices and the servers who might push information to them. The PAP allows the PI to communicate with the PPG. PPG provides access control, including identification and authentication of the PI. The PPG gateway also parses the content to detect errors in control information and, in some cases, errors in content. The PPG provides client discovery for the push initiators, including discovery of the capabilities of a potential recipient of the pushed information. Address resolution and binary encoding permit transmission of the pushed information to a client. Protocol conversion provided by the PPG allows the disparate partners in the communication to interact. The Push OTA Protocol connects the WAP client to the PPG. Multicasting and broadcasting allow the same

information to be pushed to multiple recipients (WAP Push Architectural Overview 2001).

Security

There are four aspects to security in general network communications:

Privacy. Content is visible only to the intended recipient and both parties have confidence that privacy is protected. This is addressed with various levels of encryption. The degree of confidence required will be weighed against processing costs to determine the appropriate level of encryption to use.

Integrity. Content is not modified between leaving the sender and arriving at the recipient's device. Digital signatures allow a document to be verified as being the same as was transmitted. A hash code is computed over the document and sent as part of the signature. If the hash code check on the recipient side does not produce the correct results, the document has been modified.

Authentication. The sender's identity can be verified with very high degree of confidence. Passwords, authentication, and digital signatures identify the originator.

Nonrepudiation. The sender cannot later deny having sent the information. Digital signatures are the primary tools for binding the sender to the document or resource as sent.

The WAP architecture includes a Wireless Transport Layer security specification, which includes a view of the wireless network access environment as shown in Figure 8. The figure shows both pull and push proxies. Network access is achieved in one of two modes: push or pull. Some examples of push technology are familiar: pagers, Short Message Service, and e-mail notification when a user has signed up for the notification service. The user chooses this form of intrusion in order to remain aware of new activities or special offers. Additional push services are anticipated as the wireless Web develops.

End-to-end security is accomplished in the wired Web through secure socket layer (SSL) encoding. In that approach, a secure link is created end-to-end, between the sender and the receiver. Intermediate processing units, such as routers, do not see the content of the message and only participate in routing the message from source to destination.

In the wireless Web, things are more complex. The client and server usually do not communicate directly, but they rely on proxy or gateway machines to provide necessary translation and retransmission services. The proxy intervenes between the WAP enabled wireless device and the TCP/IP and HTTP process-enabled server. Thus, security questions must include the degree of trust between the content provider and the gateway and between the client and the gateway, as well as between the client and the content provider.

WAP includes WTLS, the Wireless Transport Layer Security. WTLS is used to provide secure service between the client device and its pull gateway. WTLS is used for server authentication. Client authentication, when

Figure 7: Push framework (WAP Push Architectural Overview 2001)

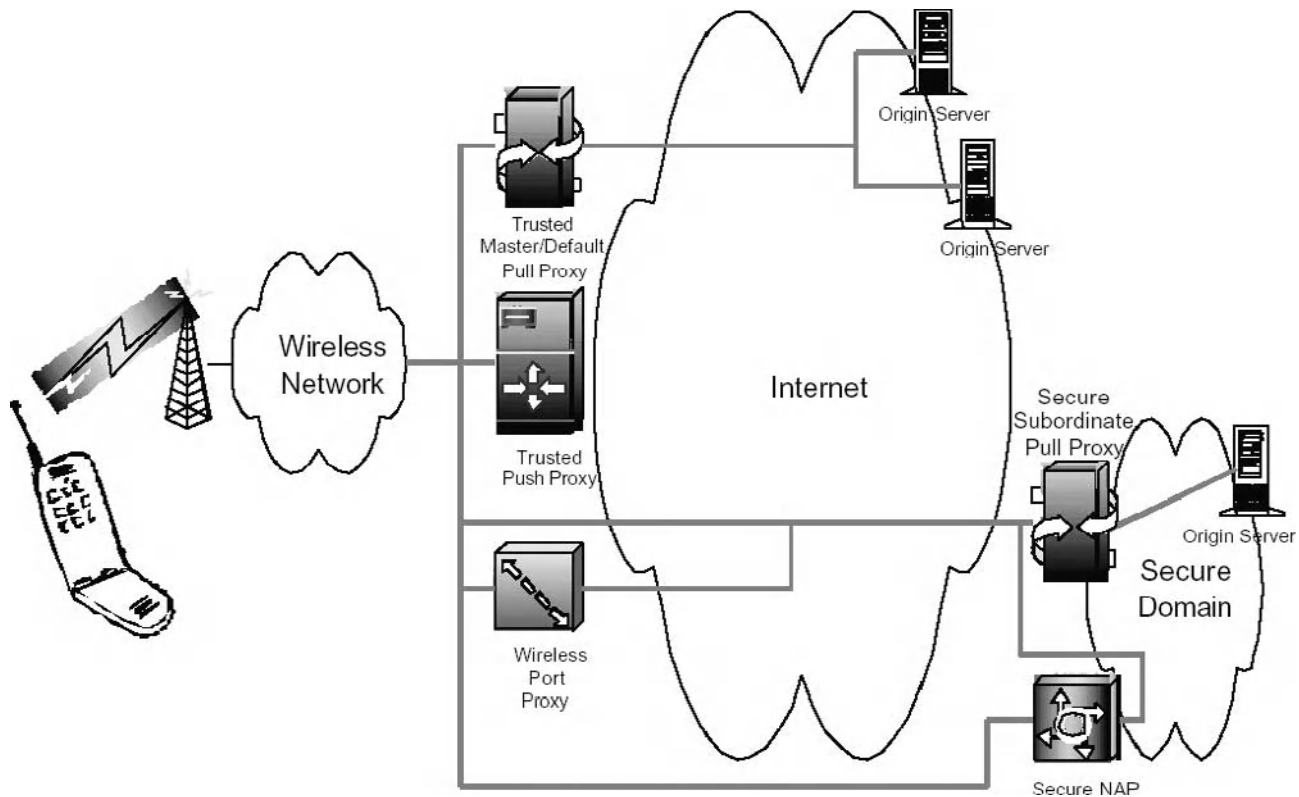

Figure 8: Wireless Network Access Environment (application Protocol 2000)

required, is left to existing mechanisms. Nonrepudiation is left to the application and can rely on existing techniques. Control in the push environment requires establishing trust between the client and the push proxy. The push proxy uses existing techniques to assure security with data providing servers.

The extra step involved is the use of a gateway between the client and the information provider. This introduces another factor into consideration of overall security. WTLS addresses security between the device and this pull gateway. Existing Web security mechanisms are used to provide security between the gateway and the service and/or data provider.

SSL is used essentially to provide secure services over the wired internet and WTLS (WAP 1.x) is a layer meant for the wireless applications using WAP. WTLS has been replaced by Transport Layer Security (TLS) as part of WAP 2.0 specifications. It provides an end-to-end encryption between the client and the server.

Mobile Access to Information Resources

The Web has a wealth of information and is taken for granted as an information and communication resource. Similarly, mobile devices have become part of daily life. Access to existing Web pages is one of the goals for handheld/mobile devices. But most of the information a mobile user may need will be dynamic. A mobile user might want to know what the traffic is just ahead or how to get from here to there. In combination with other features like

Geographic Positioning Systems (GPS), an application can address the questions. When mobile users query their bank balances before making a purchase, strong encryption must protect the data transferred without unduly impacting the amount of time required to get the answer. Mobile users can also query stock quotes, credit bills, and can browse the Internet for other querying activities.

WAP Access to Databases—An Example Using the BioWAP Protocol

BioWAP is a service for handheld devices using WAP providing access to major bioinformatics database and analysis programs. For example, BioWAP provides instant access to a protein sequence database.

Large projects often generate a vast amount of data that must be stored, analyzed, and organized. The data can be stored in Internet databases and data analysis can be made here. Usually WML is used for information exchange and to provide access to the data and services from the Internet. The BioWAP protocol and database access diagram shown in Figure 9 illustrate the concepts that apply in general.

In the example, the service requests are compiled by a WAP gateway and are then sent to a WAP terminal. The Web server is very essential in the BioWAP service. It handles user's requests, then analyzes and transmits the results to the user through the WAP gateway. The Web server in BioWAP provides tools for analysis and search. The response from the server is sent back to the gateway using WML, which then compiles the WML response and delivers it to the user.

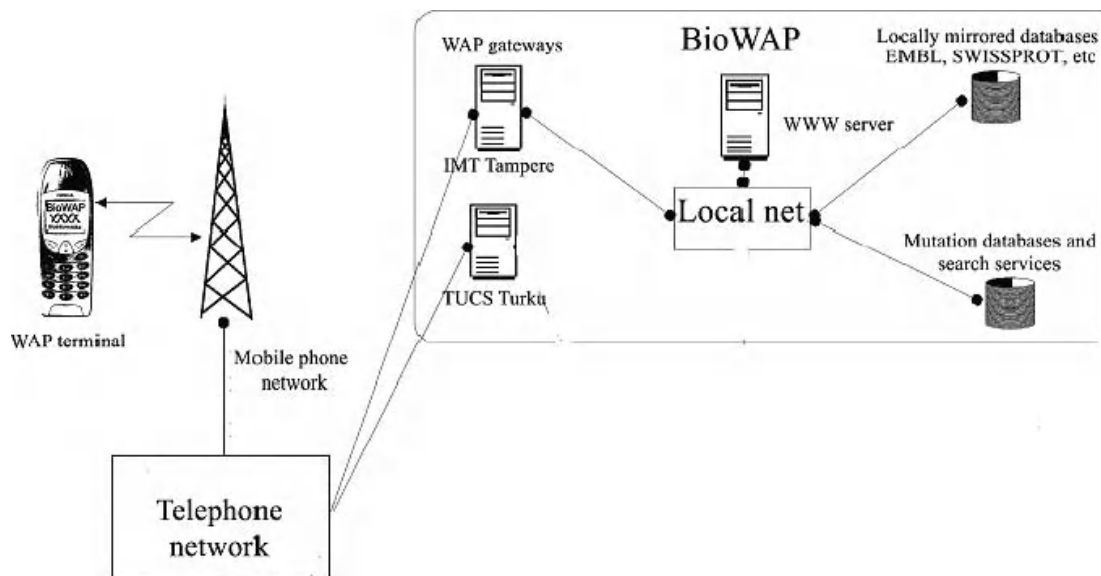

Figure 9: Mobile access to a database: the BioWAP example (Riikonen et al. 2002)

Example Applications

WAP offers the opportunity for a wide spectrum of applications in contexts ranging from automobiles to health-care. At present, WAP enabled phones can be used to request information on personal bank accounts, stock quotes, and user specific details from various organizations. Also WAP can play an important role in health care by providing necessary patient records to visiting nurses/doctors through handheld devices. A few example applications are described below.

Automobiles—Information Related to Location, Weather, and Traffic Conditions

Current traffic, weather, and location can be sent to the system in a car by a broadcaster. WAP, which was developed especially for the use in mobile and wireless networks, is well suited to use in the area of traffic monitoring. Cars can be information centers as opposed to being only transportation entities. When the driver enters a car, the current road and weather conditions are cached in a Personal Digital Assistant (PDA). The digital audio broadcast sends data to the systems in the car about the weather and traffic conditions prevalent at the moment. The Personal Travel Assistant (PTA) helps the driver to navigate. The PTA and the PDA then calculate the shortest route for the trip and set the route accordingly for the PTA. (Bechler & Schiller 2000)

Home Health Care—Connecting the Visiting Nurse to the Hospital Information System

WAP devices can serve as a mobile access terminal for general inquiry and patient monitoring services (Hung 2000, 2003). With this system, a nurse can view the patients' monitored physiological parameters on WAP devices. The system will provide acquisition, transmission, and deposit of the physical information of the home care patient into a database. If the nurse sees a need for adding more

information to the database based on current situations, he or she can do it by keying it through the WAP device. A relational database stores the patient's records. Operation cost is low due to the availability of WAP phones. A WAP-based health care system can have the following applications: ECG browsing, blood pressure browsing, patient record browsing, clinical and hospital information inquiry, and doctor's appointment browsing. Third generation mobile phones have improved the feasibility of such systems by providing greatly increased data transfer rates.

E-mail: Filtering, Notification, and Supporting Input and Output Requirements

Handheld devices provide easy access to e-mail accounts without the bulk of full laptop computers. Although cell phones and PDAs support the necessary POP and SMTP protocols, they are limited by the characteristics of these devices. Currently users can read, compose, delete, and forward messages from their mobile phones (Milasinovic 2003, Rao 2003).

Because the touch pads and the keypads on the cell phones are clumsy to use, most of the e-mail services do not ask the user to key in the login details. During the notification procedure, users are provided with a WAP link that contains a unique identifier (UID) which can be used for a one-time login procedure. The user just has to follow the provided link and it will connect the user to the mailbox.

Because of limited storage space and bandwidth, wireless handheld devices benefit from filtering of incoming mail. When the mail application downloads the e-mail headers, it scans the headers and applies the e-mail filters. The users can choose among several built-in filters or can create their own filter list. Based on the user's filter options, mail filtering eliminates unnecessary mails sent to a wireless handheld device. Some mail client applications notify the user about a piece of mail being delivered.

Location-Aware Advertising

Location-aware applications are those in which the location of a person or an object is used to focus on an application or service (Hakkila and Isomursu 2005). A mobile commerce application can make use of location aware services. Consider this example wherein a consumer has previously received a digital coupon from a shopping mall on her handheld device or a PDA. So once she has this coupon, the push initiator on the server can push data to the mobile device. The consumer, if interested, may ask for driving directions from her current location to the nearest mall. Upon arriving at the mall, the shopper is given more details regarding the store location. Once she is in the store, further information about the products and offers is sent to the PDA. Also the aisle and shelf where the product is situated can be sent to the PDA. Within each store, the handheld device may read a store guide which gives information about special offers and also has customized information about specific individuals. All of these can be accomplished using WAP.

Mobile Banking Transactions

A user with a WAP-enabled mobile phone can connect to the bank via the device. The proxy or the gateway in the structure converts the WAP protocols into the protocols suitable for the Internet. The user interface is similar to what a user sees online, but can be browsed using a mini browser. The most important aspect of an online banking structure is security. General security requirements include confidentiality, entity authentication, data authentication, and non-repudiation.

A WAP-based banking application allows users on the move to access accounts and make transactions. The transactions are recorded in a database, similar to what might happen when users access accounts from any online system. Using the WAP Push feature, a daily bank statement or alert can be sent out to a particular WAP device. Most of the leading banks have WAP-enabled services in use. TLS can provide end-to-end encryption between the client and server. TLS is part of the WAP 2.0 specification (Claessens et al. 2002).

Course Registration System

Course registration is usually done by the students either online through the Web or by filling out forms in the registrar's office. Using a WAP-based course registration system, a student can register using a handheld device and can also check all the related matter about the course like grades, assignments, and so on (Qadah and Al-Zouabi 2005).

A server database holds the information about the courses and the students. Additionally a course delivery system is present on a Web server. This course delivery system has the code/intelligence required to interact with the user as well as the database system. The student can initially start making queries to the server by keying in related text for course names. When a match is found by the Web server, it sends it to the Gateway which in turn formats it using the WAP protocol before delivering it to the user. If the student is aware of the course number, a simpler retrieval takes place. Also the server is programmed with all the prerequisites for a given course. The server makes sure the students have

completed a prerequisite before assigning them to the requested course. The course registration system can be extended to a grade delivery system as well. At present only a limited number of universities have implemented this system.

Java and WAP

Currently Java is being used to develop WAP applications. Java 2 Micro Edition (J2ME) is a specification used to develop Wireless Applications. Mobile Information Device Profile (MIDP) is also an open specification which combines Java and other Web technologies. Java Servlets and Java Server Pages (JSP) are used to develop dynamic WAP content on the server side.

MIDP programming is used to develop Java applications for WAP. It is a combination of the Java programming model and the Web programming model. It is analogous to applets in Java. MIDP files are also called MIDlets and they run using preinstalled MIDlet management software. Applets are destroyed once they are run but MIDlets stay on the device after running. The MIDlets basically serve the purpose of displaying objects on the screen of the handheld device. A sample program is given below.

```
import javax.microedition.midlet.*;
import javax.microedition.lcdui.*;

public class VillanovaMIDlet extends MIDlet
{
    TextBox box;

    public VillanovaMIDlet() {
    }

    public void startApp() {
        display = Display.getDisplay(this);
        box = new TextBox("Villanova
University", "Department of Computer
Science ", 20, 0);
        display.setCurrent(box);
    }

    public void pauseApp() {
    }

    public void destroyApp(boolean
unconditional) {
    }
}
```

The program displays the contents as shown in Figure 10. The program creates a MIDlet and displays the text encapsulated by the box object.

Messaging Services and WAP

Short Messaging Service (SMS) is a Global System for Mobile Communication (GSM) service which allows users to send text messages from one wireless device to another. Messages are sent using a store and forward mechanism. The messages are forwarded to a Short Message Service Center (SMSC) which tries to send the message to the recipient. If the recipient is not available the message is stored in the SMSC. When the user becomes available, an attempt to send the message is again made, but the

Figure 10: A sample MIDlet display

message delivery cannot be relied upon. The messages may be lost at times and may never reach the destination. A best possible delivery effort is agreed upon before the SMS is originated. Transmission between the SMSC and phone can be done using TCP/IP or using other protocols. Different languages must be encoded using the Unicode format. News alerts, financial information, and other information are the content commonly sent using SMS.

An extension to SMS is the Multimedia Messaging Service (MMS) which is a standard used for sending messages which include audio, image, video, etc. The Open Mobile Alliance (OMA) is responsible for its standardization. The initial transfer of content from the client device to the Multimedia Messaging Service Center (MMSC) is done using HTTP. Then a notification is sent to the recipient's device using a WAP push. Either an immediate or delayed delivery is performed based on the user's requirements. With the convergence of WAP and SMS, powerful applications are being built that enables communication between devices.

SMS or MMS can act as a carrier for information transfer. Data can be sent between devices that are WAP compliant using SMS or MMS. For certain applications using SMS, interactive interfaces are not that appealing when compared to the interfaces generated with WAP. Both SMS and WAP have a role in building applications that are efficient and visually appealing.

XHTML MP and Wireless Markup Languages

WML and XHTML MP are the popular scripting languages for scripting WAP applications. WML, though not the current standard (WAP 1.x) for authoring, is used on some client applications. The content below describes the basics of WML and introduces the card format for information delivered to handheld devices. Further sections introduce the use of XHTML MP, the current standard (WAP 2.0) and its syntax. Because the newer standards are based on the older WML, we begin with a brief description of WML basics.

WML Basics

As we have seen, normal HTML specified Web pages are seldom suitable for display on handheld wireless devices. The WAP protocol suite includes an XML language designed to specify items for display on these devices. The Wireless Markup Language (WML) borrows heavily from HTML, but eliminates features not suitable for these devices and adds functions that address the screen size and user input options.

The first difference to notice is the paradigm of presentation. Where the Web metaphor is a page, the WML metaphor is a card. A single application display is a deck of cards, much as people sometimes use in gathering research data in a library. Each card contains a small amount of content and may contain links to other cards in the same deck, cards in other decks, or even to conventional Web pages.

An example application is the best way to illustrate and introduce WML. The example is developed using the Open wave SDK, available free from <http://www.openwave.com>. The simulated displays for a mobile phone are part of the SDK. The appearance of output from a WML specification will vary according to the nature of the device on which it is displayed. The example allows a client to obtain information about a particular city. The first screen identifies the application. The WML code for this initial card is shown in Figure 11.

```
<?xml version="1.0"?>
<!DOCTYPE wml PUBLIC "-//PHONE.COM//DTD WML
1.3//EN" "http://www.phone.com/dtd/wml13.dtd">
<!-- WML file created by Openwave SDK -->
<wml>
  <card id="Start">
    <p align="center"> <b> City information</b>
  </p>
  </card>
</wml>
```

Figure 11: First WML card specification

The first two lines of this WML file reflect the XML connection. This identifies the XML version and allows valid compilation of the file. The actual WML specification begins with `<wml></wml>` and ends with `</wml>`. Like other XML applications, each WML element has both an open and close component. Notice that the `<p>` (paragraph) tag must be closed by `</p>` unlike ordinary HTML. The `<wml> . . . </wml>` tags mark the beginning and end of this deck. The deck may contain as many cards as the application requires. Each card is specified by `<card> . . . </card>`. The `<card>` tag shows an id for this card that can be used to reference it from other cards. The title of this card has been centered by an option in the `<p>` tag and made bold by the usual ` . . . `. Figure 12 shows the simulated output for this first WML example.

Next, the example adds options to the display. Each option will consist of a link to another card with further information on the chosen topic. This requires a list. The list in this application will allow the user to choose weather information, restaurants, museums, or information about public transportation. Each option in the list specifies the next card to visit if that option is selected. The entire select list goes inside a `<p> . . . </p>` tag element. The list code follows:

Figure 12: Simulated display of first WML code

```
<select name="listname">
  <option event = "link"> Label </option>
</select>
```

The syntax for the list in which each option links to another card in the current deck is

```
<?xml version="1.0"?>
<!DOCTYPE wml PUBLIC "-//PHONE.COM//DTD WML
1.3//EN" "http://www.phone.com/dtd/wml13
.dtd">
<!-- WML file created by Openwave SDK -->
<wml>
  <card id = "Start">
    <p align="center"> <b>City information
  </b> </p>
    <p align="center">
      <select name="categories">
        <option onpick = "#weather"> Weather
Forecast </option>
        <option onpick = "#restaurants">
Restaurant List </option>
        <option onpick = "#museums"> Museums
</option>
        <option onpick = "#trans"> Public
Transportation </option>
      </select>
    </card>
</wml>
```

The listname joins this set of options with a common title. "Label" is displayed on the user screen. The *event* is the occurrence that causes this item to be selected from among the options available. The *link* identifies the card to be displayed next. The following code includes a list of options for city information. Each link is relative, in fact is a reference to a card in the same deck. The syntax for that reference repeats the HTML syntax for a jump to a location in the same page.

Figure 12 shows the simulated output for this first list. Immediately, the constraints of the small screen become apparent. The wordy descriptions are too much for this device to display well. In Figure 13, the descriptive text is shorter and the list fits comfortably on the screen.

The user selects a list option by means of the arrow keys or by pressing the number corresponding to the chosen list entry. In Figure 13, the *Museums* entry is chosen. Pressing the button under the check mark will make the selection. To continue the application development, the additional cards are added to the deck. The empty cards are shown below:

```
<?xml version="1.0"?>
<!DOCTYPE wml PUBLIC "-//PHONE.COM//DTD WML
1.3//EN" "http://www.phone.com/dtd/wml13.
.dtd">
<!-- WML file created by Openwave SDK -->
<wml>
  <card id = "Start">
    <p align="center"> <b>City information</b>
  </p>
    <p align="center">
```

Figure 13: First list attempt

```

<select name="categories">
  <option onpick = "#weather"> Weather
</option>
  <option onpick = "#restaurants">
Restaurant List </option>
  <option onpick = "#museums"> Museums
</option>
  <option onpick = "#trans"> Public
Trans. </option>
</select>
</p>
</card>
<card id="weather">
  <card>
<card id="restaurants">
  </card>
<card id = "museums">
  </card>
<card id = "trans">
  </card>
</wml>

```

The initial display looks no different, but now there is a card corresponding to each choice. The cards are empty currently, ready to be filled in with relevant information for this application.

Basics of XHTML Mobile Profile (XHTML MP)

XHTML (Extensible Hypertext Markup Language) MP is a language designed for Web clients having resource constraints. This is the current client scripting language used for developing client applications. XHTML MP is targeted at devices such as mobile phones, handheld devices, PDAs and pagers. It is an authoring language meant specifically for handheld mobile devices. XHTML Mobile Profile is based on the modules defined by modularization of XHTML. It can be considered as a subset of XHTML 1.1, which is based upon XHTML Basic. XHTML MP adds support for a scripting environment and helps in

binding scripts to events. It also includes XHTML forms. (Passani) XHTML supports the use of style sheets which allow authors the control while presenting contents. The second part of this section describes this feature more fully. The subsection below has the tags listed with the families to which they belong.

Families of Tags

Table 1 has XHTML MP Tags organized based on the XHTML modules. The table represents the XHTML basics modules and the tags and attributes that belong to the particular modules. Table 2 shows tags that were not part of XHTML Basic but were introduced in XHTML MP.

Style Sheet

Style information can be specified for a document in one of the following three ways:

External Style Sheet

Internal Style Sheet

Inline Style Information.

External Style Sheet. The external style sheet is always associated with the link element, a special XML processing instruction. The example below associates the external style sheet "mobile.css."

Table 1: XHTML Tags Organized by XHTML Modules

Module	Element
Structure	body, head, html, title
Text	dfn, div, em, h1, h2, h3, h4, h5, h6, kbd, p, pre, q, samp, span, strong, var
Hypertext	A
List	dl, dt, dd, ol, ul, li
Basic forms	Form, input, label, select, option, textarea
Basic tables	caption, table, td, th, tr
Image	img
Object	object, param
Meta information	Meta
Link	Link
Base	Base

Table 2: XHTML Tags Introduced in XHTML MP

Module	Element/Attributes
Forms	Fieldset, optgroup
Legacy	start attribute on ol, value attribute on li
Presentation	b, big, hr, i, small
Style sheet	style element
Style attribute	style attribute

```
<?xml-stylesheet href="mobile.css" media="handheld" type="text/css"?>
```

When an external document uses the link element, certain values for the rel attribute are specified. When rel="stylesheet" or rel="alternate stylesheet", the type attribute specifies the style sheet language. In the example below, a link element is used to relate the external style sheet "mystyle.css"

```
<html>
  <head>
    <link href="mystyle.css" type="text/css" rel="stylesheet"/>
    . . .
  </head>
  . . .
</html>
```

Internal Style Sheet. The style information can be part of a document internally. The style element has an attribute called style which specifies the style sheet language. The following shows an example of an internal style sheet.

```
<html>
<head>
  <style type="text/css">
    P { text-align: center; }
  </style>
  . . .
</head>
  . . .
</html>
```

Inline Style. Style information for a single element can be set using the style attribute. This is called inline style. The style attribute is part of the core attribute set and is therefore available on every element in XHTML Mobile Profile. The default style language is the Wireless CSS [WCSS]. In the example, inline styling information is applied to a paragraph element:

```
<p style="text-align: center">. . .</p>
```

Building Menus

Menus are used for interaction in all wireless applications. A menu denotes a list of navigating choices through an interface. Choosing a menu item leads to a new page being loaded and displayed to the end user. Menus can also be associated with numbers and the user can choose a number to select the particular menu choice.

```
<?xml version="1.0" encoding="UTF-8"?>
<!DOCTYPE html PUBLIC "-//WAPFORUM//DTD XHTML Mobile 1.0//EN"
"http://www.wapforum.org/DTD/xhtml1-mobile10.dtd">
<html xmlns="http://www.w3.org/1999/xhtml" xml:lang="en">
<head>
  <title>Contacts - R</title>
```

```
<link href="style.css" rel="stylesheet" type="text/css"/>
</head>
<body>
Pick contact:
<ol>
  <li><a href="contact.jsp?id=32" accesskey="1">Dr.Cassel</a></li>
  <li><a href="contact.jsp?id=45" accesskey="2">Dr.Beck</a></li>
  <li><a href="contact.jsp?id=21" accesskey="3">Dr.Goelman</a></li>
  <li><a href="contact.jsp?id=17" accesskey="4">Dr.Perry </a></li>
</ol>
</p>
</body>
</html>
```

This list builds a numbered menu. The <xml> tag defines the version of XML, the encoding format, and the document standards that are followed. The <link> tag links to an external style sheet style.css. The tag encloses the options, which are listed individually wrapped by the tags. The access key attribute of the <a> tag numbers the options. The above list displays a list of contact names that are displayed in the form of a menu in the image (Figure 14) below.

The above display has each name displayed as a link. When clicked, each takes the user to the corresponding JSP page as scripted in the XHTML listing previously.

Figure 14: Menu display

Text Flow Using XHTML MP

Web browsers are used for displaying data to a user. XHTML MP provides the needed functionality. The following listing shows how text can be displayed on a browser. The image (Figure 15) following the listing displays the user defined text included in the listing. The text can be enclosed between the <body> and the <p> paragraph tags.

```
<?xml version="1.0" encoding="UTF-8"?>
<!DOCTYPE html PUBLIC "-//WAPFORUM//DTD XHTML
Mobile 1.0//EN"
"http://www.wapforum.org/DTD/xhtml-mobile10
.dtd">
<html xmlns="http://www.w3.org/1999/xhtml"
xml:lang="en">
<head>
    <title>Plain Text</title>
</head>
<body>
<p>
This is a tutorial on WML, XHTML MP and WAP.
So now is the time to learn WAP
    <div style="text-align:right"><i>Openwave
</i></div>
</p>
</body>
</html>
```

The <pre> tag is used to display preformatted text. Most of the tags collapse the white spaces in and around the text. But when it is desirable to keep the existing text

Figure 15: Text display

Figure 16: Display using <pre> tag

formatting intact, the <pre> tag is used. The text below wrapped around the <pre> tag is displayed in Figure 16.

```
<body>
<pre>
Villanova
University

        has
        a sports
team by name
Wildcats.
</pre>
</body>
```

Apart from these tags, the following tags have important functionality when formatting text.

Headers: The header tags can be used to hierarchically arrange data at different levels. Also they can be used to enlarge characters to make them appear as a heading. The heading tags have the same name and function as in standard HTML. Below are the different header formats.

Emphasis Tags: Tags commonly found in HTML are used here as well. Some of the important text formatting tags are: for bold, <q> for quote, for bold, for emphasis, <i> for italics.

Links: The anchor tag is the most important of all the tags in XHTML MP. Text can be enclosed between the tags and the href attribute of the tag has the URL as in standard HTML.

Developing Forms Using XHTML MP

A form allows the user to enter information like names, addresses, and phone numbers and then select items using drop down boxes and radio buttons. The different tags involved with forms are embedded between the `<form>` and `</form>` tags. The form tag has the name and path of an external script, which helps in processing the data collected by the form. Below is a listing that shows the various form elements displayed in image (Figure 17).

```
<form action="/servlets/processform"
method="get">
<p>
<select name="category">
  <option value="blended" selected="
selected">Product:</option>
  <option value="books">Books</option>
  <option value="music">Music</option>
  <option value="dvd">DVD</option>
  <option value="vhs">VHS</option>
  <option value="vhs">Ringtones
</option>
</select>

<br/>

Keyword:<br/>
  <input type="text" name="key" value=""
format="" /><br/>

Are you a ACME Co. Member?<br/>
  <input type="radio" name="member"
value="yes" checked="checked" />
```

Figure 17: Form created using XHTML MP

```
Yes<br/>
  <input type="radio" name="member"
value="no" />
No<br/>

Zip code:<br/>
  <input type="text" name="minutes"
value="" format="NNNNN" />
<br/>

Do you accept ACME conditions?<br/>
  <input type="checkbox" name="accept"
checked="checked" /><br/>
</p>

<div class="centered">
  <input type="submit" value="Submit"/>
</div>
</form>
```

The `<select>` tag presents a list of items to be displayed in a drop-down box. The `<input>` tag with the attribute type set to `text` displays the text box below the label "Keyword." When the type is set to `radio`, radio buttons appear instead of text boxes. Only one of the radio buttons can be selected from a range of buttons. The form can be submitted by clicking on the submit button. The submit button can be displayed using the `<input type="submit">` tag. When the submit button is clicked, the action attribute of the form tag is executed. Images can be embedded inside forms and Web pages in general using the `` tag.

Images and Objects

The `` tag is used to place pictures on WAP pages. The syntax and attributes are very straight-forward.

```

```

The `alt` attribute provides a label for the image. The `src` attribute mentions the path from which the image is to be fetched. Height and width tags specify the height and width of the image in pixels.

Using the `<object>` tag, the media type can be played or viewed within the WAP Browser.

```
<object data="music.wav" height="20"
width="20" title="Play" type="audio/x-wav"
standby="loading" />
```

The above tag has a "wav" file, which is to be played in WAP Browser. The remaining attributes, height and width, specify the height and width of the control on the screen. The title attribute controls how the soft key label appears on the device. Figure 18 shows the effect.

DESIGN CONSIDERATIONS

Design considerations have figured in several parts of this article. The following points summarize the major issues.

Figure 18: Display of an object on a WAP browser

Considering Speed

Bandwidth is still much lower for handheld wireless devices than for wired Web connections. As a result, bits that do not contribute to the user achieving a desired result will not be well regarded. Recent advances in the design of engaging and entertaining Web pages will not serve this population. The application developer must focus on getting the message across in as few words, symbols, and images as possible.

There is another consideration related to speed besides the limitation of bandwidth. It is important to consider where and how these devices are likely to be used. Often device users walking or taking time out from a meeting or other activity. They are not seated comfortably at their desks or in their living rooms. The other constraints on these systems mean they are not generally the first choice for casual browsing. The user wants some information and wants it now. This is not the environment for enticing the visitor to explore the wonders of the site. A prompt and pointed response to a request will suit the users' needs and bring those users back another time.

The Small Screen

The small screen has been mentioned a number of times and an example was shown in the illustrations. While bandwidth and resolution on the screen will improve, the screen will not get larger. That is because smallness is a prized feature of many of the WAP enabled devices. Some devices, such as PDAs have larger screens than others. However, application developers must assume that the screen is small and may be viewed in difficult lighting

environments. Interaction must be designed for ease of use under these circumstances.

Navigation

Because of the small screen, the basic model of a "document" becomes a deck of cards. Each card contains a small amount of information and usually contains an opportunity to link to another card in the same deck or in a different deck. WAP provides all the power of the Web to reach sites and to initiate processes on remote services. However, the results of those server processes and the information on the Web pages will be constrained by the presentation environment. Each WAP client must have a way to interact with a specified set of events triggered by user actions. The way these are made available and the ease of user access will vary. An accept button and a button that goes back to the previous card are the most dependable constants. This can be designed using a scripting language like XHTML MP and WML. Presenting navigation options as links in a list allows the user to scroll through the choices and accept the most appropriate one.

CONCLUSION: SUMMARY AND LOOK AHEAD

WAP technology could bring about the convergence of mobile communications and the Internet. With new technology come risks and opportunities. The expectations for WAP have been high and the results have not always kept up.

Today, the vast majority of microprocessors go into embedded systems, many of which only support stand-alone applications. While the technology is there to make these appliances communicate wirelessly with each other or with humans, progress has been limited. At same time, WAP and XHTMLMP offer a general purpose, interoperable presentation platform for user interfaces.

WAP has had seen huge success in Japan. Korea is also leading the world in providing advanced WAP services. WAP on top of the Code Division Multiple Access (CDMA 2000) network has been proven to be the state of the art wireless data infrastructure. Other technologies like Multi Media Messaging and Short Message Servicing (SMS) have combined with WAP to further drive the protocol. Since 2003 and 2004, mobile service providers including Vodafone and T-Mobile have used WAP to provide wireless services, resulting in a resurgence of the protocol.

WAP is sometimes considered to have failed to live up expectations and hype. It was earlier touted to be the Web on the phone. One contributor to the difficulties of developing WAP applications is the lack of good authoring tools. Despite the investment that companies have started to make in WAP, there are concerns about the technology's usefulness and appeal. There are challenges on both the side of the devices and the side of the protocols. However, the potential use of these devices is of increasing interest, providing motivation for work in developing an increasingly sophisticated set of resources.

A complicating issue in the deployment WAP applications is the protocol itself. The protocol was initially designed to support a range of different protocols like SMS, MMS, and IP. This has led to the development of a very complex protocol. The design was ambitious and the full realization of the expectations remains a challenge. WAP provides a mechanism for bringing the Web to small portable devices that have characteristics that make them unsuitable for interfacing to regular Web pages. There remains a great opportunity to realize this potential.

GLOSSARY

BioWAP: An illustration of the use of WAP protocols to access database resources. BioWAP provides access to bioinformatics databases and analysis programs.

ISO OSI Reference Model: The standard seven layer model of communication between computers over a network. The base model is often modified for specific purposes but serves as a well-known base reference.

Location Aware Advertising: Integration of global positioning services and WAP protocols to allow broadcast of information specific to a physical location. Examples might include warnings about road conditions or traffic problems or offers of special discounts on merchandise at a nearby business.

Mobile Information Device Profile (MIDP): A specification that combines Java and other web technologies to produce MIDlets. These are run using special software on the handheld device. They are similar to applets, but they remain on the device after an initial run.

Performance Enhancing Proxies: An intermediate process provider that serves to translate between the Web materials designed for standard desktop or laptop computers and the limitations of handheld devices.

Pull Information Delivery: The delivery of content initiated by a request from the receiver.

Push Information Delivery: The delivery of content initiated by the sender without an explicit request from the receiver.

Wireless Application Environment (WAE): The part of WAP corresponding to the Application Layer of the ISO OSI Reference Model. It consists of the Wireless Markup Language (WML), XHTML Mobile Profile, Wireless Cascading Style Sheets (WCSS), WBXML, WMLScript, vCard and vCalendar.

Wireless Application Protocol (WAP): A collection of protocol standards for communication between web servers and handheld mobile devices.

WBXML: A compact, binary representation of XML documents for efficient transmission without loss of semantic content.

Wireless Transport Layer Security: A protocol element used to provide secure service between a client and a pull gateway. WTLS provides server authentication.

INTRODUCTION

The ATM technology is being intensively deployed to public and private communication networks. ATM is attractive because of its potential capability to support a variety of services and the development of applications (e.g., multimedia) that require constraining quality of service (QoS). ATM was designed for transmission over fiber-optic links characterized by extremely low error rate (of the order of 10^{-12}). As wireless services become popular, wireless extension to ATM will be needed to adapt the ATM technology to a wireless environment that will allow mobile users access to the network resources. The main advantage of wireless ATM (WATM) technology will be the seamless radio extension of ATM to mobile users and the support of multimedia communications. To deploy WATM, many issues first have to be addressed. Some of the major problems are related to: (a) the QoS provision in the presence of high bit error rate at the radio links; (b) the mobility management of mobile users; and (c) the provision of handoff services.

With respect to deploying ATM on wireless links, two different approaches are observed: the first approach, which is supported mainly by the ATM Forum, involves foreseeing the presence of ATM connections toward the wireless end user. This approach is discussed in this chapter. The second approach, which is preferred for International Mobile Telecommunications-2000 (IMT-2000) and Universal Mobile Telecommunication System (UMTS), involves foreseeing the use of ATM only in the core transport network and avoids the transport of ATM on the air interface.

WATM consists of three main components: a) the ATM switches, which integrate user-to-network interfaces (UNI) and network-to-network interfaces (NNI) with additional mobility support; b) the control and switching units, which provide mobility-related signaling (e.g., registration, de-registration, location, and handoff), handle data routing, and incorporate typical ATM switches; and c) the base stations (BSs), or access points (APs), which are attached to the control service unit (CSU) ports by

means of high bandwidth links. The APs are responsible for the adaptation of ATM cells to radio packets (and vice versa) and their transmission over the radio link. Mobility management has two distinct components: a) location management, which translates user names to their current location, and b) handoff, which is a handover control for dynamic rerouting of connections when the terminal crosses cell boundaries. Figure 1 depicts a graphical overview of the WATM architecture.

A mobile terminal (MT) can move within the coverage area of the base station and communicate with other MTs, in the case of MT-to-MT calls, or with traditional ATM terminals, in the case of MT-to-fixed-terminal calls. The operation of the CSU component is supported by a database (DB), which is designed to keep track of the current location and status of MTs. The CSU also can be used for security services such as terminal authentication. Finally, the CSU is in charge of processing the MT-originated signaling messages related to mobility and the standard signaling messages for the setup and release of connections. On the other hand, the BSs work as traffic concentrators on the uplink and as splitters on the downlink.

To provide integrated broadband services to a variety of mobile users and applications, WATM supports the full range of ATM services, including the constant bit rate (CBR) service and the variable bit rate (VBR) service.

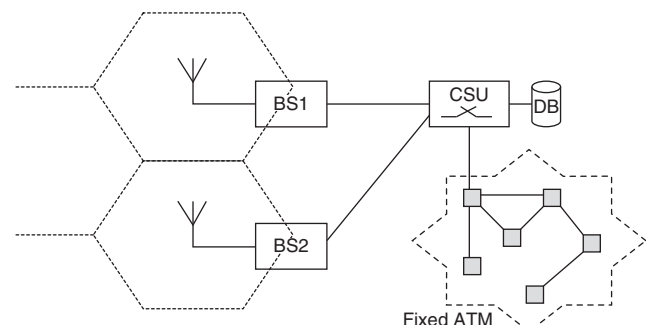

Figure 1: WATM architecture

Although the QoS of these services should be identical to those provided by a wired ATM, its provision may be constrained by the radio link access and the degree of terminal mobility. However, the benefits of WATM access technology should be observed by mobile users as a service and accessibility improvement. By providing the essential characteristics of ATM transmission, WATM can improve the performance of the QoS provision that is not achieved by other wireless networks.

The objective of this chapter is to discuss the major issues in WATM networking. The chapter is organized as follows: the first section introduces the foundations of WATM, followed by the requirements of WATM to fulfill its objectives. Next, we discuss the architecture and components of WATM. The following section introduces the protocol stack of WATM, followed by the extension of QoS in wireless systems using characteristics of ATM. We discuss the mechanisms applied to the wireless environment and adapted to WATM (e.g., handover and location management), and present the standards and implementation of products such as the wireless ATM network demonstrator (WAND) and rapidly deployable radio network (RDRN) before concluding the chapter.

FOUNDATIONS OF WATM

To make WATM easy to understand, we discuss in this section the major concepts and features of ATM and wireless technologies.

ATM Technology

ATM offers a high-speed network that integrates all types of information transfer, including real-time and non-real-time traffic. ATM represents one of the most important technologies for the wide area interconnection of heterogeneous systems. Its network is composed of a large number of switches that are connected to one another via network-to-network interface. This networking technology provides high bandwidth at low costs compared to traditional approaches that support different services by building separate dedicated networks. However, implementing ATM networks is not necessarily cheap because it requires optical backbone networks and high-speed ATM switches. The information transferred between network nodes is packaged into fixed-sized cells of 53 bytes, in which 5 bytes are reserved for the header, which contains the control information. Figure 2 depicts the structure of an ATM cell header, including six major fields. Field GFC represents the generic flow control, which is used to provide local functions such as identifying multiple stations that share a single ATM interface. The GFC field is typically not used and is set to a default value. The fields VPI and VCI identify the virtual path and the virtual channel, respectively, that the cell takes to reach its destination by passing through a series of switches. The PTI field represents the type of payload contained in the cell. The first bit of the PTI field indicates whether the cell contains user or control data. If the cell contains user data, the second bit of the PTI field indicates congestion, and the third indicates whether the cell is the last in a series of cells that represent a single AAL5 frame.

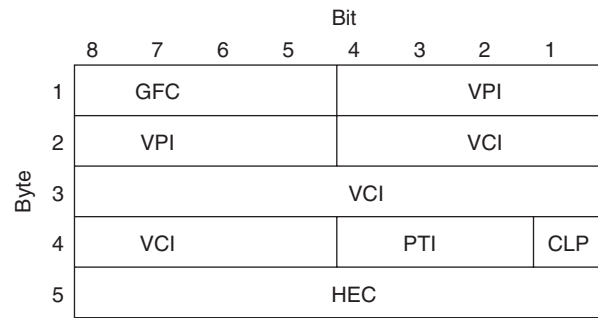

Figure 2: ATM cell header format for the UNI interface

The CLP field is a bit that is used to distinguish between high- and low-priority cells. It indicates whether the cell should be discarded when it encounters extreme congestion as it moves through the network. Finally, the HEC field indicates a checksum over the header.

ATM provides connection-oriented communication, meaning that before cells are transmitted, a connection is established between the source and destination. When the connection is set up, all cells are sent along the same route to the destination. Therefore, routing decisions take place only at the connection setup. Cells travel along virtual channels (VCs) and virtual paths (VPs); virtual paths contain a large number of virtual channels. Cells are switched according to the VP/VC identifier values contained in the incoming data. A routing table at each switch indicates the outgoing VPI/VCI for each incoming virtual channel (or incoming VPI/VCI). Hence, the VPI and VCI fields (present in the cell header) are altered as the cell goes through the switches. The typical routing protocol in ATM is the private network-to-network interface (PNNI), which divides the nodes into collections of nodes called peer groups. Peer group leaders represent their peer group members to the rest of ATM network. PNNI provides a mechanism for building hierarchies of peer groups and reduces the routing process to the construction of a route between peer group leaders and the delivery inside a peer group.

ATM signaling is the process used to establish and release ATM connections. PNNI signaling is used by an edge switch to set up the virtual channel in each switch along the path of that connection. When an end user submits a request for connection setup, the request is sent to the switch to which the end user is connected. The switch then acknowledges the request reception by sending back a call proceeding message. Between the switches along the path to destination, a PNNI setup message and a call proceeding message are sent until the destination switch is reached. If the destination agrees to set up a connection, it sends back a connect message. The connection is then set up and data can be sent.

Traffic Classes

ATM networks can be deployed to provide the transport of different data types. Five classes of services are defined in ATM:

- **Constant bit rate (CBR):** This service aims to transport CBR traffic with a fixed timing separation between

data units. This service is appropriate for conventional digital voice and CBR video traffic.

- **Variable bit rate–real-time (VBR-rt):** This service is intended to transport VBR traffic combined with rigorous real-time requirements, such as video conferencing. The traffic is known to have a transmission rate that varies in time; however, ATM cannot introduce a delay variation between cells. This means that ATM tightly controls the average cell delay and the delay variation so that they do not exceed a certain value. However, occasional cell loss can be tolerated.
- **Variable bit rate–non-real-time (VBR-nrt):** This service does not provide a guaranteed delay bound. It provides a guaranteed average, but a certain amount of jitter can be tolerated. Nrt-VBR would be appropriate for data traffic, which has less strict delay requirements but still needs throughput guarantees like a local area network (LAN) interconnection.
- **Available bit rate (ABR):** This is a best effort service; neither rate nor delay can be guaranteed. The network will allocate a connection as much bandwidth as possible to meet the minimum values of the traffic contract. This service allows an ATM system to fill its channels to the maximum capacity when CBR or VBR traffics are low.
- **Unspecified bit rate (UBR):** This service does not offer any service guarantee. UBR is similar to ABR, but it does not guarantee minimum rate and bound on the cell loss rate. Typical use of UBR is best suited for IP packet transfer, file transfer, backup traffic, and e-mail delivery because they do not make any constraint on delivery.

To implement the aforementioned services, ATM uses a layer called the *ATM* adaptation layer (AAL), which adapts the incoming traffic to the ATM layers (including the physical support). As shown in Table 1, AAL is divided into two sublayers: the segmentation and reassembly (SAR) sublayer and the convergence sublayer (CS). Whereas the former sublayer transforms traffic into cells and classifies them, the latter provides traffic synchronization and error detection (Deane 1996). Four types of adaptation can be distinguished: AAL1, AAL2 (Makké et al. 2002; Villaseñor-Gonzalez et al. 2002), AAL3/4, and AAL5. Table 1 discusses the major functions provided by the AAL for each type.

QoS Parameters

When a virtual channel is set up, the desired QoS is specified to make up a traffic contract between the end user and the network, which is guaranteed as long as the transmitted traffic on a connection conforms to the traffic descriptors specified in the traffic contract. To make a traffic contract well specified and to allow the negotiation of service parameters by the end user and the network, a set of QoS parameters is normalized for ATM. The QoS is specified by the following parameters:

Minimum cell rate (MCR): This parameter represents the minimum cell rate that the customer can accept.

Peak cell rate (PCR): This is the maximum rate at which the sender is expecting to send cells.

Sustained cell rate (SCR): This measures the required cell rate averaged over a long time interval.

Table 1: Major Functions of AAL Types

AAL Type	Targeted service	Details
1	Emulation of circuit	<ul style="list-style-type: none"> The SAR uses the first byte of each cell to define a field of sequence in it protected by CRC.
2	Variable bit-rate video	<ul style="list-style-type: none"> The SAR allows the support of low-speed data or voice. CS provides for error correction and transports the timing information from source to destination. This is achieved by inserting time stamps or timing information into the convergence sublayer-protocol data unit.
3/4	Variable bit-rate data service	<ul style="list-style-type: none"> The SAR uses four bytes per cell (sequence, priority, CRC, multiplexing). CS adds information about delimitation of the data.
5	ABR data service	<ul style="list-style-type: none"> CS generates a CRC and other identifiers (for the message). SAR uses the bit PTI of the heading cell to identify the last cell of a message.

Cell delay variation (CDV): This parameter describes how uniformly the cells are delivered.

Cell delay variation tolerance (CDVT): This parameter describes the maximum acceptable difference in arrival time deviation from the expected cell rate.

Cell transfer delay (CTD): This parameter is the average interval of time (or average end-to-end delay) that a cell needs to travel from source to destination.

Cell loss rate (CLR): This parameter measures the fraction of sent cells that are lost or arrive so late at their destination that they are considered ineffective.

Cell error rate (CER): This represents the fraction of cells that arrive at the destination with one or more errored bits.

Cell misinsertion rate (CMR): This measures the fraction of cells that are delivered to the wrong address due to errors in the header of the received cell with respect to the number of all received cells by the destination.

Severely errored cell block ratio (SECBR): This is the ratio of N-cell blocks of which M cells contain errors.

Wireless Networking

Two categories of wireless systems can be distinguished in the literature. The first category uses point-to-point links with different bit rates and varying operational frequencies. The second category uses wireless data transmission with cellular architecture implemented with various techniques including code division multiple access (CDMA), space division multiple access (SDMA), time division multiple access (TDMA), and frequency division multiple access (FDMA). The wireless transmission systems that offer a roaming service include cellular data systems. Table 2

presents the data rates that correspond to different network and wireless techniques (Bertoni et al. 1994; Correia and Prasad 1997).

Low bit rates are offered by mobile networks that allow mobility and roaming possibilities. For example, the GSM data services offer limited QoS with respect to the QoS required by multimedia applications. Many improvements have been provided to GSM to improve its data transmission services (e.g., GPRS and HSCSD). On the other hand, the UMTS was developed to provide better QoS and security. It achieves bit rates up to 2Mb/s locally, and lower bit rates in wide area coverage. UMTS represents one of the significant improvements for the second-generation (2G) wireless systems (Raychaudhuri 1996).

Wireless Provision of QoS

QoS provisioning in wireless networks cannot use the paradigm defined for fixed networks unless it is enhanced. This is mainly because of the severe variation in the network resources availability in a wireless connection. This variation is induced by two natural factors: wireless link and mobility. In contrast to links of conventional wired networks, wireless links suffer from a high bit error rate (BER), which results in a packet loss on the wireless medium. It also induces packet delay and jitter; if error recovery mechanisms are utilized. Typically, the BER of a wireless link can be improved by designing better transmission and reception wireless subsystems. However, it is commonly agreed that there is a limit to the level of improvement because there is trade-off between BER and bandwidth in a wireless link.

On the other hand, mobility effects occur through fading and handoff. The fading characteristics of a wireless channel vary greatly based on time and spatial dependencies.

Table 2: Wireless Data Rates

Wireless Data Access	Achieved Data Rates	Mode
Digital European cordless telephone (DECT)	<1 Mbits/s	per user
GSM data (general packet radio service [GPRS], high-speed circuit-switched data [HSCSD], cellular digital packet data [CDPD])	<144 kbits/s	per user
UMTS	>5 Mbits/s	shared
Industrial, scientific, and medical (ISM)-band WLANs	>54 Mbits/s	shared
High performance local area network (HIPERLAN)	<20 Mbits/s	shared
Wireless fidelity (WiFi)	>100 Mbits/s	shared
Worldwide Interoperability for Microwave Access (WiMax)	>2 Gbits/s	shared

Added to interference, fading will force the transmission link to vary its bandwidth. Moreover, as a mobile terminal roams in a wireless network and hands off from one BS to another, the wireless (e.g., the bandwidth in the new radio cell) and wired resources (if needed) would change. This can result in a major change in the availability of the network resources. Additionally, depending on the overhead of the signaling system and the rerouting protocol, the QoS-level degradation due to the connection moves during handoff. Therefore, the major issue in wireless and mobile networks with respect to QoS provisioning is to deal with the variation in resource availability. A solution to this depends on the type and level of QoS that a mobile terminal wants. For example, in a video connection, the quality of video received at the mobile terminal is closely dependent on packet loss and jitter. A solution for this is to require the mobile network to match the QoS guarantees of a fixed network, regardless of the variation. This means that the service providers have to increase the degree of pre-provisioning in the network to a high degree to mitigate packet delays and losses. This solution is unacceptable because it does not accept varying degrees of QoS guarantees and generates a great number of packet losses. A better solution would be to change the fixed service guarantee contract between the application (or mobile terminal) and the network, and to design applications so that they can accept varying degrees of QoS guarantees and generate packet flows consisting of subflows, each with a different level of loss and delay sensitivity.

Finally, the large differences between wired and wireless links in terms of BER and bandwidth result in the statement that BSs are essential for the provision of high levels of QoS. The interface between the wired part and the wireless link at a BS must make certain that the packet-level QoS of a subflow is met according to its predefined quality requirements requested by the aforementioned application. One of the mechanisms that may be needed for this is a multiple-access control protocol that maintains a minimum level of availability for the shared wireless resources. The provided availability has to offer better protection for the transmission of packets over the wireless link by implementing the required QoS of the subflow, because a unified error-control scheme would not be suitable for all subflows.

Routing is another source of QoS dissatisfaction in wireless and mobile network. Routing protocols must take into consideration the required QoS. First, every handoff operation will induce a period of time, during which the rerouting process is executed (it lasts from the time the handoff is initiated until its completion). During this period, packets cannot be transmitted and may be delayed or lost. The length of this period is dependent on the rerouting protocol. Second, the newly established route (after the handoff is performed) might not provide the same level of QoS as the one that was left.

Benefits and Problems of WATM

Because ATM provides end-to-end considerations of traffic performance, it reduces the network complexity and improves its flexibility; this is why WATM deploys a cell-relay paradigm developed for ATM. It has been adapted

as the next generation of wireless architectures (Tomar and Singh 2005; Raychaudhuri 1996). WATM was intensively studied in the 1990s because it offered certain benefits. Some of these benefits are as follows:

WATM benefits. ATM technique can combine multiple media transmissions into wired networks while scaling well with different network types such as LAN, metropolitan area network (MAN), and wide area network (WAN). The motivation for integrating ATM into the wireless environment is the fact that wired communication networks can be dominated by ATM networks and the QoS can be managed via ATM-like contact. Therefore, the packet transmission, in which the packet processing time can be minimal, is generally used by WATM. One fundamental characteristic of ATM networking is the provision of bandwidth on demand. This proves that, until WATM, application development was constrained by the fact that data transmission schemes could not support various QoS parameters; in addition, the maximum data transmission bandwidth with which the applications have to be interfaced is relatively small. ATM has removed these constraints, and bandwidth has become less expensive as a result. Additionally, ATM provides good support for various traffic classes (Raychaudhuri 1996).

WATM access aims to improve service and accessibility to mobile terminals. To preserve the characteristics of ATM transmission, WATM improves performance and QoS in the ways discussed earlier. The enhancement is not attainable by conventional communication systems like cellular systems, cordless networks, or wireless LANs. Integrating ATM in a wireless environment has many technical benefits over the wireless networks that are not offered by any other networking technology.

WATM problems. The current WATM approaches impose some limits on the development of wireless solutions based on ATM. Even still, ATM shows great promise as the infrastructure technology of choice for wireless networks. There are, however, different areas in which ATM developments have been less important. One of the major issues is that ATM presents a highly complex technology. As explained previously, ATM was developed to be used with virtually unlimited bandwidth, low bit error rates, and point-to-point connections. The radio medium, used in mobile networks, features an inherently limited bandwidth, a high bit error rate, and a contending nature. Using small cells and radio access in the Gigahertz band can overcome the limited bandwidth; this provides very high bandwidth per radio cell and mobile terminal. Advanced channel coding and ARQ schemes in a logical link control (LLC) protocol can handle the high error rates, whereas a medium access control (MAC) protocol can monitor the use of the broadcast medium (Wasi 1995).

The ATM payload is relatively small. Therefore, the addition of any single byte in the header will greatly affect wireless channel throughput efficiency. The ATM header in the wireless medium may be compressed for the purpose of reducing the packet overhead. However, this compression will generate additional complexity at the wireless/wired interface (where the compression/decompression process

takes place) and will increase the total data transmission time (Tomar and Singh 2005).

WATM REQUIREMENTS

The typical objective of most WATM proposals is to design a wireless network of integrated services and provide extensions of ATM-based service capabilities in a relatively transparent, seamless, and efficient manner. This means that the proposed WATM systems should support a reasonable range of services, bit rates, and QoS scenarios. Two classes of requirements are of note: system requirements and user/operator requirements.

System Requirements

As shown in Figure 3, the minimal set of the requirements that WATM should comply with can be divided into four different classes: a) the network access requirement; b) the system functions and signaling requirements; c) the requirements of offered services; and d) the requirements imposed by the supported environments. This section discusses the major requirements in these classes that make WATM special (Jabbari et al. 1995).

Network Access Requirements

The set of requirements imposed by the network access capabilities generates different issues. The first issue imposes the need to extend ATM signaling to the wireless end. The second issue necessitates mobility management by the WATM network. To resolve these issues and allow for the establishment of WATM connections, two approaches have been considered. The first approach is called *ATM over the air*, and the second is called the *interconnecting of wireless and wired parts*. For both of these approaches, it is possible to preserve the transmission characteristics of ATM to the customer access node.

One of the reasons not to use ATM in a wireless environment is that it is far too expensive to extend ATM to the user terminal compared to the advantages this can provide. To reduce the extension cost, existing installations can be used with the upgrade of the switched connections with wireless interfaces to obtain more bandwidth for terminals. A second reason is the amount of modifications needed for the standard broadband integrated

services digital network (B-ISDN) signaling to properly handle the terminal mobility, because mobile users have to be able to move within the coverage area provided by the BS. The problem is that the current signaling standards do not support mobility of terminals.

System Functions and Signaling

ATM control processing is based on three functions: the call admission control, the call control, and the traffic policing. These functions have to be implemented within the WATM network in order to consider the wireless and mobility effects. In addition, other functions have to be added because of the wireless link and user mobility. The following aspects should be considered when implementing these functions:

- **Mobility:** This is an important aspect for the mobile terminals. WATM should be able to offer mobility services by allowing handoffs of acceptable speeds within the mobile customer access network. It is the responsibility of the host network (public ATM network) to offer roaming service between radio domains, because this service has been implemented by mobile telecommunication systems. There are many ways to implement mobility management, including a large spectrum of the existing implementations. Global system for mobile communications (GSM), for instance, solves the problem using special registers (home location register and visitor location register). Another way to implement mobility on WATM is to base it on the advanced intelligent network technologies. UMTS selects one technology to perform mobility management. Both the register and intelligent network approaches would be interesting solutions for WATM.
- **Security and privacy:** Security needs are important for transmission protection and end-to-end application security. Wireless transmission imposes new constraints on security compared to other transmissions because specific attacks can be performed on the wireless medium (e.g., replay attacks, spoofing, etc.). In WATM, packets are transmitted via the wireless interface so that the protection level is hard to determine because of the complexity and power requirements of security algorithms. However, a minimal service needs to be provided: the authentication of mobile terminals and BS.
- **Traffic and resource management (RM):** These aspects are necessary when wireless access is used. As explained in the previous section, resource availability may vary because of the mobility (handoff), fading, and bit errors. Although ATM has included some traffic and congestion management functions, it is important to extend these to the wireless part. The customer resource management may need to be considered in the planning phase of the network access system. The improvement of the radio resource operation has to be considered by the network.
- **Call admission control (CAC):** The CAC is a mechanism that decides whether a new call can be accepted or rejected. CAC may have to consider more than one virtual path at the same time and should depend on the architecture of the wireless access system. This introduces a certain level of complexity because wireless systems

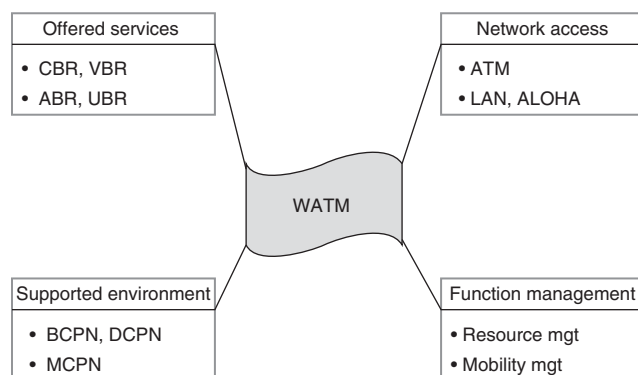

Figure 3: WATM requirements

contain multiple radio transceivers. Moreover, the traffic policing units have to ensure that all calls correspond to the traffic. The *discarded cells* are a metric that can be used to measure the QoS over the wireless links. However, these may not show the real loss of frames at the AAL5, for example, because if one of the cells in a frame is discarded by the AP, whole frames may be discarded on the AAL5 level.

Offered Services

WATM systems have the possibility to achieve high rates (exceeding 20 Mbits/s each), and they can provide support for multimedia services. The wired part of the WATM is the ATM network, which provides services that cope well—ATM networks offer flexible platforms to applications by supporting different service classes. In order to be able to offer an attractive wireless platform to multimedia applications, all of the service classes defined for the fixed ATM network should also be supported over the wireless link.

ABR is attractive for the WATM access system, especially for data communications, because it offers a way to control the cell flow using resource management cells. If the radio link is congested, the source can be notified to decrease the generated traffic. In the case of interference or fading, the minimum requirement for ABR traffic is the data loss or the impossibility of congestion signaling. On the other hand, the UBR service does not suffer from this phenomenon because QoS is not guaranteed for UBR traffic contract.

Supported Environment

There are several kinds of environments in wireless technologies that can be designed to support a mixture of bit rates and QoS parameters. The following categories of environments are maintained by the Resource Assessment and Conservation Engineering (RACE) research program (Raychaudhuri 1996):

- The Domestic Customer Premises Network (DCPN). This environment is characterized by the incapacity to update the location. In this case, the system is reduced to a radio extension of the network. The WATM service is provided only in small, isolated areas, perhaps individual cells. No mobility is provided in this environment.
- The Business Customer Premises Network (BCPN). BCPN defines a private environment, which is characterized by a private network covering the buildings of a (large) company. BCPN offers PABX-like functions within the radio-covered area. Therefore, functions like handoff and paging are implemented in this multi-cell environment. However, the mobility management functions are reduced to location update and handoff (fading, for example does not have to be taken into consideration).
- The Mobile Customer Premises Network (MCPN). The MCPN environment provides coverage within a mobile unit. MCPN provides the functions of DCPN and BCPN and adds the interface that is required to provide the access to the fixed network.
- The Public Network (PN): The PN has similar characteristics to a public mobile network such as the GSM

network. It also provides functions for paging, location updating, roaming, and handoffs.

User/Operator Requirements

Communication services are becoming more common and are today used by people in both their work and daily lives. The basic requirement for the mobile user is easy to define: users require *ubiquitous access* to advanced communication services, regardless of location and mobility. There should be no significant difference in the type of services accessed by a user in any of the locations the mobile user can visit. On the other hand, communication services offer more and more advanced multimedia characteristics to enhance their ease-of-use and efficiency. The content of these services is not usually offered by the network operator but by an external service (or content) provider; regardless of who is the service provider, the service should be presented to users with the appropriate QoS.

The degree of mobility that must be supported by WATM is a concern. WATM focuses on the needs of mobile users. For that reason, it is necessary that it not only provide a wireless link to ATM but also support a high level of user mobility, so that communication is possible wherever the user is located. When moving between remote locations, the user mobile terminal might be powered off and thus may be restarted in various locations. This means that mobile users expect the WATM to support roaming and handoff support. In fact, the user needs to be able to move around in every location while maintaining active communication. To achieve seamless roaming capabilities for a user, WATM needs to support a number of radio interfaces.

Seen from the operator point of view, integrating mobile and fixed communication serves one the major concerns of the operator, which is the cost-effective service provision. The growth in mobile communication varies from one network to another and can be difficult to predict. Thus, an operator may need the increase to be made using progressive and cost-effective measures. This means that the initial investment to enhance the fixed infrastructure for mobile communication might be acceptable and that following investments can be done in a progressive way. This allows small companies to effectively employ wireless technology and allows large networks to increase coverage as demand grows. Therefore, the main operator requirement for WATM is to facilitate maximal sharing and reuse of fixed ATM resources and functions. In private networks, this will be a significant way to reduce the cost of advanced networking solutions for integrating wireless technologies. In the public networks, this constitutes a key requirement for the operator to stay alive.

Finally, WATM needs to support the full multimedia, multiservice semantics of fixed ATM. This is required to maintain the basic service requirements on WATM to support multimedia. Moreover, mobility should be transparent to the parties involved in communication. Communication between a fixed and a mobile terminal should be possible even if the fixed terminal has no special knowledge of the other user's mobility. In addition, WATM needs to support a number of radio interfaces to achieve seamless roaming capabilities for a user.

WIRELESS ATM ARCHITECTURES

Most of the literature on this subject discusses different solutions, models, and architectures for WATM; this section presents the major developed architectures. Several architectural components—including the fixed wireless components, mobile end users, and mobile switches—are also discussed in this section for the sake of clarity.

Wireless Integration

Integrating mobility with the existing set of ATM standards requires a compatibility of the wireless protocols with the fixed ATM architecture. To integrate wireless, a solution has to maintain the fixed ATM architecture as a subset of the WATM architecture. From a user perspective, the concept of integration means that a network appears as a seamless and coherent entity. When accessing a service, a WATM user should not need to be aware of whether access is by way of optical cables or radio links. From a network design perspective, integration handles a number of network issues. Integration includes using the same network functions and protocols for common operations, sharing network infrastructure, and providing the same set of services.

Based on the reason that integration of mobility into fixed ATM is the core concept of WATM, the integration of mobility can be reflected in the architectures defining WATM through the identification of three main alternatives: a) reuse of the fixed ATM architecture; b) added mobility to the ATM architecture; and c) enhanced ATM architecture. The first alternative assumes that the WATM can, without loss of efficiency, reuse the fixed ATM architecture. Using this approach, the WATM architecture will basically be equal to the fixed ATM architecture. This approach is generally infeasible when mobility is required, because this would mean that wireless operation does not introduce any functional changes to the ATM fixed network architecture.

Using the second alternative, WATM simply introduces additional functions into the network architecture in such a way that authorizes these functions to remain clearly separated from the fixed network aspects. If the features are isolated from the fixed ATM, WATM could be introduced by simply adding a separate, parallel architecture for it. This alternative has one desirable feature: it allows WATM to be introduced as a modular addition to fixed ATM. In its simplest form, this alternative is to a certain extent implausible, because the wireless operations and ATM functions interoperate to achieve mobility objectives, which does not cope with the simplicity of the interface that the wireless architecture should have with fixed ATM.

The third alternative appears to be the most likely way for wireless system architectures to integrate with fixed ATM network—it aims at modifying the already existing architecture. For some aspects of WATM related to mobility management and QoS provision, this approach is unavoidable. In cases in which modifications are necessary, it is commonly agreed that the amount of modifications can be kept very limited and that enhancing the fixed architectures is achievable. Unfortunately, a couple of problems

are inherent in extending the ATM architecture: a) equipment built based on earlier standards might not be able to use the new architecture; and b) equipment conforming to the enhanced architecture might suffer from performance penalty, if used only to support fixed communication.

Besides the aforementioned alternative architectures, it is likely that WATM will develop through an evolutionary process in which many of the aforementioned alternatives can be used for a given architecture at different times. A typical evolutionary scenario to build the architecture could start with a WATM simply reduced to the fixed ATM architecture. In the next evolutionary step, wireless functions should be considered. At this point, wireless specific solutions could be considered and developed; however, a solution could potentially be acquired from the shelf. This might lead to the definition of a separate architecture for WATM according to the second alternative. Finally, as wireless systems become more widely used, the next step could allow fixed users to make special provisions for communication with wireless users. In this step, provision would be made for the fixed users who need access to some of the functions and capabilities of the WATM architecture.

Architectures and Components

User requirements of WATM are captured in the *service architecture*, and the operator requirements are captured in the *network architecture*. The requirement that WATM should provide the same service paradigm as a fixed ATM network is taken as the starting point to discuss the relevance of the ATM service architecture and modifications required to adapt it to mobile systems.

The purpose of service architecture is twofold: first, the service architecture must be defined in terms of a sufficiently small set of points or regions within the continuum formed by all possible user requirements. If a modular definition of the services combines simplicity with flexibility and power of expression, the network designer's task is made easier without compromising the initial user requirements. Second, service architecture provides a simple model of the capabilities of a network to potential network users. End users can benefit from this, because they need a clear view of network capabilities in order to subscribe to a network. Therefore, the service architecture typically performs a descriptive function. On the other hand, the service architecture has more central importance to the application developers and network operators, because end users are protected from the details of network use and operation. The network architecture can be defined as a set of constraints on the implementation architectures. It must be feasible to incorporate the set of functions defined by the implementation architectures into the nodes defined by the network architecture. Five architectural components can be considered in the following, including the fixed wireless components, mobile end-user devices, and mobile switches. The mobile end-user devices communicate directly with the fixed network switching devices via wired or wireless channels. Mobile switches can be connected either directly or via another mobile switch to the fixed network switches (Cong 1997).

- *Fixed wireless components:* In fixed wireless LANs, there are fixed end-user devices and switching devices, which are used to establish connections via wireless channels. In these kinds of situations, the data transmissions are made on the wireless medium, assuming that no mobility management is provided.
- *Mobile terminals:* In the digital cellular and wireless LANs, the mobile end user devices communicate directly with the fixed switching devices using wireless channels. To support the ATM connections, it is essential that the end-user devices have a wireless terminal adaptor, which communicates with the wireless access point (WAP) in the fixed switches.
- *Mobile switches with fixed end users:* Wireless channels connect end-user devices with switches. In this case, the end-user device and the switch are considered mobile equipment. There can be more than one end-user device attached to one switch. The switch has to establish connections with the fixed components using wired or wireless channels. To this end, WAP and wireless terminal adapters are used to enhance fixed and mobile switches.
- *Mobile switches with mobile users:* When the end user wants to establish a connection, it first requests it from a mobile switch, which then sets up a connection with the fixed network switches either directly or via another mobile switch. WAPs and wireless terminal adapters are also needed to support mobility. This scenario also considers end-user devices as mobile.

REFERENCE MODEL

To add mobility to the ATM network, extensions to the ATM protocol can be made. Moreover, the key functionalities of the planes and layers in the ATM protocol architecture have to be adapted to the WATM context.

WATM Protocol Architecture

WATM protocol architecture is based on the integration of radio access and mobility features within the standard ATM protocol stack. The general philosophy for adding mobility and broadband radio access to ATM is outlined in Raychaudhuri (1996), as depicted in Figure 4, which shows that a WATM system may be partitioned into two relatively independent parts: a mobile ATM infrastructure and a radio access segment, each of which can be designed and specified separately. This facilitates standardization

by multiple organizations and allows for a progressive evolution of radio access technologies without having to modify the core mobile ATM network specification.

The protocol architecture defines what protocols are used at the different interfaces of a system. Since the first design of the open system interconnection (OSI) protocol reference model, every protocol definition has followed the layered approach. Therefore, the protocol architecture describes the different interfaces of the network in terms of layered stacks. To achieve integration of wireless with fixed ATM, the layered stacks of wireless and fixed ATM should coincide for those interfaces that are common. Two domains of interest can be identified in the protocol architecture: the user and control planes of the ATM network. The protocols in the user plane transport data, whereas the control plane protocols are used for signaling. Typically, the control and user planes converge at some layers (e.g., the ATM layer, in the case of ATM) so that the lowest layers of the planes are common. In ATM, the ATM and upper-layer protocols are handled in an end-to-end manner.

To be well matched with ATM, WATM should therefore embrace these key ATM protocols. The protocol architecture for WATM must allow fixed systems to communicate with mobile wireless nodes using the ATM protocol suite. In the protocol architecture for ATM, the control plane architecture is rather complicated. A distinction between the UNI and the NNI must be made for the control plane. In the UNI control plane, the connection control protocol—generally referred to as ITU Q.2931—is used to control connection setup and release. The integrated layer management interface (ILMI) protocol, defined by the ATM Forum, is used for interface management and functions such as address assignment. At the NNI in private networks, the PNNI protocol replaces the Q.2931 per ATM Forum recommendations. For public networks based on the ITU signaling standards, a protocol architecture exists for the NNI. The architecture is based on the Signalling System 7 and uses four layers.

To extend the protocol architecture of ATM to support wireless users, two objectives have been considered: a) any modifications to the user plane protocol stack should occur below the ATM layer in order to achieve end-to-end transparency; and b) signaling should remain compatible with fixed ATM where common functions exist but be implemented as a modular extension for mobile-specific aspects. In the case of protocol architectures at the UNI, significant convergence can be seen. Especially with regard to the user plane, most existing proposals are rather similar. In these proposals, the major modification

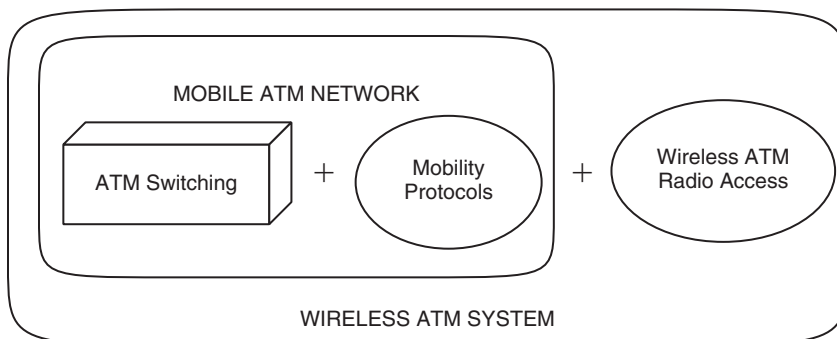

Figure 4: Modular protocol architecture of WATM system

has been to substitute the physical layer at the radio interface with three radio protocol layers, as illustrated by Figure 4. The three layers replacing the physical layer aim to provide a sufficiently constant QoS over the radio interface in order to ensure a radio link performance that maintains end-to-end QoS.

In Figure 4, the radio physical layer (PHY) is in charge of the radio transmission operations, including modulation and power control. This layer is rather dependent on the targeted frequency range and cell size. Schemes for physical layer and implementations exist in a number of frequency ranges, including the 2.5 GHz ISM band, 5 GHz, and 40/60 GHz. The PHY layer is split into two sub-layers: the physical layer convergence procedure (PLCP) and the physical medium dependent (Hyon 2001). Many types of modulations can be used such as equalized quadrature phase shift keying (QPSK), quadrature amplitude modulation (QAM), multi-carrier orthogonal frequency division multiplexing (OFDM), and spread-spectrum CDMA. Some researches focus on the use of CDMA because it can offer multiple advantages, including a good capacity and better-quality signal. Selection of modulation method and bit rate for the WATM PHY is an important standardization for both ETSI and the ATM Forum (Deane 1996).

The medium access control layer permits the radio interface to be shared by managing multiple access and contention (Sfikas, Apostolas, and Tafazolli 1998; Yuan and Motoyama 2002). In WATM, an important feature of the MAC is to allow each ATM virtual channel to be separately processed at the radio interface, so that the virtual channels can be provided with the requested QoS also at the radio interface. Distributed MAC protocols, used in existing wireless LANs (WLANs), do not provide adequate performance for WATM. This is partially a result of: a) the fact that the LAN protocols assume a much bigger payload to work efficiently; and b) the current LAN protocols cannot provide performance guarantees as required by the ATM QoS model. Subsequently, a number of new MAC protocols addressing the above issues have been proposed for this purpose. A large set of these protocols control resources by means of a single entity. If this entity is attentive to the QoS requirements of the different active connections, it can provide QoS guarantees.

The following features have to be considered to design a MAC protocol (Cong 1997):

- *Access mode:* In general TDMA, FDMA, CDMA, or a hybrid combination of these schemes can be used for accessing WATM. Because of the use of the statistical TDMA in ATM networks and because of the high bandwidth observed on the physical channel, a hybrid TDMA/FDMA scheme has been proposed in WATM systems.
- *Duplex schemes:* Two duplex schemes are considered for WATM systems: time division duplex (TDD) and frequency division duplex (FDD). TDD presents the disadvantage of generating additional overhead. However, it has the advantage of efficiency gained from the statistical multiplexing of the uplink and downlink.
- *Signaling of slot assignments:* Once the capacity allocation is determined, the slot assignments have to be signaled to the wireless terminals. This is done by grouping the

reservation messages for a specific time interval into a signaling burst.

- *Transmission of capacity requests:* To guarantee the correct execution of a service strategy, the scheduler has to be informed (often, as frequently as possible) about the status of the queues inside the wireless terminals, which is performed by the transmission capacity request messages over the uplink.

The wireless data link control (DLC) layer is naturally used to enhance the error performance of the lower layers within the QoS requirements of the connections (e.g., delay bounds). For that, error-detection and retransmission protocols and forward error correction methods have to be used (Zhong et al. 2001). Mechanisms such as selective retransmission are used in different DLC proposals. Considering the control plane, the proposal views are divergent to some extent. The main theme appears to be that the fixed ATM connection control protocol is reused for the connection management. Mobility is embedded into the connection control protocol in some proposals, but most proposals use a separate protocol for mobility specific functions (see Figure 5).

To specify wireless functions, a wireless header and trailer are added over the radio link. In a wireless environment, it is necessary to use a wireless frame over the radio link encapsulating several ATM cells. This allows necessary overhead over a larger data payload. Figure 6 depicts the functions supported by the DLC layer. In the unified model language (UML) diagram, arrows show

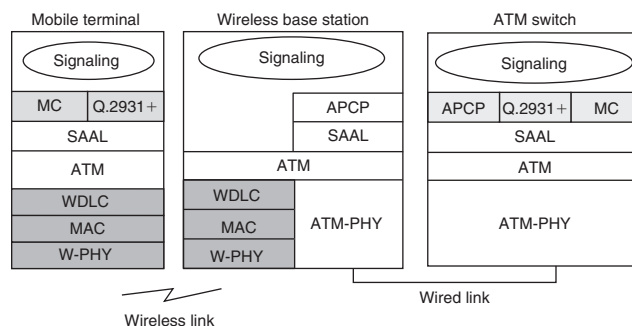

Figure 5: Control plane protocol architecture at the WATM switch UNI

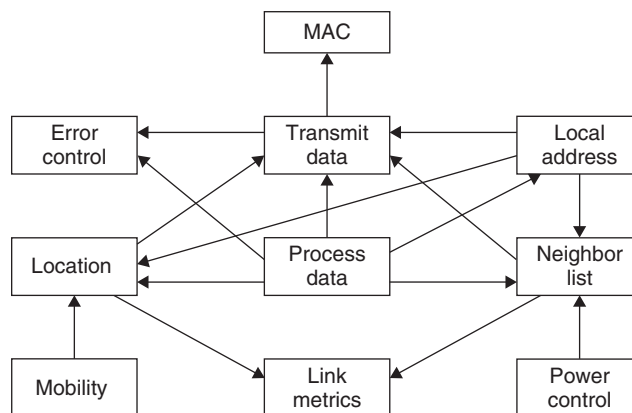

Figure 6: DLC layer architecture

the dependency among functions. For example, the data transmission function depends on MAC functions to obtain the transmission time and the used channel.

Major Functions

Figure 6 depicts the major functions implemented in different WATM architecture proposals; in the following section, we summarize the main features of these functions.

Protocol Q.2931+ refers to a generic, improved version of the fixed ATM connection management protocol (ITU Q.2931, or ATM Forum 4.0). The basic enhancements of this protocol have considered the support to handover. This enhancement only comprises two additional signaling messages. It is therefore feasible to include these messages in the basic connection management protocol. In addition, some modifications to parameters and information elements of the existing Q.2931 messages can be handled. This is required mainly to support mobile specific QoS aspects according to the service architecture. With these modifications, protocol Q.2931+ can be used for both fixed and mobile communication without significant overhead.

An access point control protocol (ACPC) is used for the interaction between the switch and the radio access system. This protocol allows the switch to control the radio access system during connection setup and handoff. The MAC protocol refers to the protocol(s) used to implement mobility control. Using a separate protocol for mobile-specific features makes the UNI protocol architecture modular. This feature is important to provide because it is in accordance with the architecture principles found in ATM, in which a number of additional protocols were proposed to achieve a high degree of modularity in the protocol architecture.

The key issues of the WATM architecture model, illustrated in Figure 6, relate to the signaling activity. The signaling ATM adaptation layer (SAAL) protocol is used to transfer the connection control protocol. Because SAAL protocol is connection oriented, it is relatively badly suited for a mobile network in which the communicating parties move between UNIs, as can happen during a handoff. This can be solved by introducing an additional network layer protocol to the WATM control plane that is capable of high-speed routing. This would allow the mobile to maintain a virtual link with the switch despite handoffs. However, a major problem occurs as a result of using a routing protocol WATM: the protocol architecture for fixed and WATM differ as far as the lower layers in the control plane stacks are concerned.

Finally, a radio resource control (RRC) is needed to support the control plane functions related to the radio access layer (RAL). The RAL should support radio resource control and management functions for the PHY, MAC, and DLC layers. The design issues of RAL include: a) control/management syntax for PHY, MAC, and DLC layers; b) meta-signaling support for mobile ATM; and c) interface to the ATM control plane (Hakan 1995). The management and control of radio resources are operated in parallel with communication control procedures. The basic management of radio resources is inherent to the radio resources control plane, whereas the overall carrier and connection

control (including radio channel activation and handover execution) is managed by the communication control plane.

QUALITY OF SERVICE IN WATM

ATM provides five QoS classes of services: CBR, ABR, VBR-rt, VBR-nrt, and UBR. Functions related to the implementation of QoS in ATM are usage parameter control (UPC) and connection admission control (CAC). Typically, UPC function is implemented at the network edges and ensures that the traffic generated over a connection conforms to the declared traffic parameters. Traffic in excess may be dropped or transported on a best effort basis. The CAC function is performed by all switches and determines whether the QoS requirements of a connection can be satisfied by the available resources.

Existing implementations of WATM have chosen to maintain the existing QoS model and allow transparent extension of fixed ATM applications to the domain of wireless access. The problem with QoS provision in WATM is that it is hard to change dynamic QoS parameters for an active connection. When a new connection is requested, a set of QoS requirements is attempted. If the specified QoS cannot be satisfied by the wireless link, the connection is rejected. QoS in WATM requires a set of cooperating mechanisms at three levels:

- *At the network:* In addition to the ATM QoS mechanisms that are assumed available on the wired network, a mechanism for QoS renegotiation is useful. This authorizes the network and the mobile terminals to renegotiate a new-connection QoS when the existing QoS requirements can be maintained during a handoff.
- *At the radio interface:* A QoS-capable MAC layer is required. The mechanisms needed are resource reservation and allocation for ATM virtual circuits for various classes of QoS, and scheduling to meet delay requirements. In addition, a mechanism for error control is needed to cope with radio link nature. Finally a CAC mechanism is required to limit access to the multiple access radio link in order to maintain QoS for the serviced connections.
- *At the mobile terminal:* Mobile terminals implement several mechanisms related to QoS provisioning. These mechanisms take place at the MAC and network layers. In addition, some mechanisms at the application layer may be needed to cope with variations in the available QoS as a result of radio link degradation and terminal mobility.

The control of the QoS is handled by a controller associated with a sender and a receiver and using a control channel. For AAL5, the used connections accept an additional QoS by passing a QoS structure. To do so, a control of the QoS parameters is independently specified by the network level; this requires good knowledge of network behavior. Because this alternative provides maximum performance from the network, it is used by WATM (Hakan 1995). With regard to the ABR service category, a flow control scheme is specified by ATM forum in the traffic management (TM) specification 4.0. The source

Figure 7: Explicit ABR flow control

periodically sends user and management cells downward to the destination, to inform a source of an ABR connection about the available bandwidth. As shown in Figure 7, the destination evaluates the congestion status and the supported cell rate of the connection at each switch and returns the resource management cells to the source.

The following two sections consider in more detail the major QoS mechanisms used at the MAC and the network layers.

MAC Mechanisms

The radiolink in WATM is typically a multiple-access channel shared by various mobile terminals. Different multiple-access technologies can be implemented with multiple access channels, as described earlier; these include a combination of FDMA and TDMA. Each radio port operates on a certain frequency band. The mechanisms include the resource reservation, the allocation mechanism, and the scheduling function (Sfikas, Apostolas, and Tafozoli 1998; Yuan and Motoyama 2002; Porter et al. 1996).

Resource Reservation and Allocation Mechanism

WATM can use a TDMA/TDD scheme for medium access. This scheme allows the flexibility to partition the frame dynamically for downlink and uplink traffic, depending on the traffic load in each direction. Typical features of this scheme include the following:

- An important part of each slot is used for forward error control (FEC).
- A separate contention region in the frame is used for mobile terminals.
- Control packets are used for bandwidth requests and allocation announcements.
- WATM cells are modified ATM cells with added data link control and cyclic redundancy information.

In the downlink direction, the WATM is transported by various ATM connections termination using different mobile terminals. After the cells arrive at the fixed network, the allocation of TDMA slots for specific connections is based on the connection traffic and QoS parameters. In the uplink, the allocation is based on requests from the mobile terminals. The transaction of cells from multiple active connections at a mobile terminal is again subject to the scheduling scheme. Both the request for uplink slot allocation request sent by the terminal and the response are carried in control packets whose format are depicted in Figure 7, in which the sequence number is used to recover from transmission losses. Request and allocation types indicate one of four classes: CBR, ABR, VBR, and UBR. The allocation packet has a start slot field, which indicates where in the frame the mobile terminal should begin transmission. The number of allocated slots is also indicated.

The data link control can be used to reduce the impact of errors that cannot be corrected using the FEC. The DLC is responsible for selective retransmission of cells with uncorrected errors or lost cells.

Scheduling Function

The objective of a scheduler is to regulate the traffic over the radio interface with respect to the declared ATM traffic parameters of the active connections. It also ensures that the delay constraints (if any) are met over the radio interface. The selection of cells for transmission is based on the service categories of active connections as well as their traffic characteristics. A connection is also serviced based on its service category. Thus, CBR connections are serviced first, followed by VBR-rt, VBR-nrt, and ABR. In addition, for each active connection that is not of type UBR, a token-based policy can be implemented. Tokens for a connection are generated, accumulated, and removed appropriately. For example, when a cell belonging to a connection is selected for transmission, a token can be removed from the related pool (Reininger, Raychaudhuri, and Hui 1996).

Scheduling can operate a selection of the cells to service on a two-pass process. At the end of a first pass, either all of the slots in the downlink portion of the frame have been used some slots are still available. In the latter case, a second pass is started, inducing a potential excess of traffic in VBR-rt, VBR-nrt, ABR, and UBR classes. To avoid overloading the scheduler, the CAC must have some knowledge of the expected load induced by handoffs so that it can limit connection admission to preserve the QoS for active connections, while not degrading existing connections at the radio interface.

At the end of the selection phase, the scheduler has determined the number of cells to be transmitted from each active connection. Some of these cells are to be transmitted uplink while the others are to be transmitted downlink. The scheduler attempts to place the cells for transmission within the frame such that the cells take place in the appropriate part of the frame (uplink or downlink) based on the delay constraint of the corresponding connection to meet. To do this, the delay allowed over the radio segment can be determined for each connection (this value can be obtained during the connection routing phase by decomposing the path delay into delays for each hop). Then, the arrival time for the cell from the fixed network is marked for downlink cells; for uplink cells, the arrival time is estimated based on the time at which the request was received from the MT.

Network and Application Functions

In this subsection, two major classes of QoS control functions are examined: the dynamic framework control and the soft control. Whereas soft control is used to support terminal mobility and maintain acceptable application

performances, the QoS framework provides mechanisms that should be able to handle the mobility and dynamic bandwidth needs (Raychaudhuri 1996).

Dynamic QoS Control

Bit rate-based metrics of multimedia applications vary significantly because of user interaction, among other things. Contributing factors for this variation include the heterogeneity of media compression schemes, the presentation quality of requirements, and the session interactivity. For this to be addressed, mechanisms that react on the dynamic variation are very helpful. A suitable QoS control mechanism would support bandwidth renegotiation to achieve high resource utilization and maintain acceptable performance. This mechanism is a key tool for supporting QoS of adaptive applications. Renegotiation may be required during handoff and when resource allocation changes are necessary as a result of instantaneous needs. An example of renegotiation mechanisms is given by VBR+, which allows multimedia applications to request bandwidth on demand (Reininger, Raychaudhuri, and Hui 1996).

Soft QoS Control

The soft QoS control service is suited for adaptive applications, which are capable of adapting their performance to available network resources. Soft QoS service consists of two parts: a usage profile, which specifies the target regime of operation, and a service contract, which quantifies the soft QoS service to be provided by the network. A usage profile might describe the media type, the interactivity model, and the mobility model. The service contract quantifies the probability that the satisfaction of a connection will fall outside an acceptable interval. While a connection is active, a dynamic resource allocation is performed. When congestion occurs, the soft QoS control mechanism reallocates resources among connections to maintain contract satisfaction. However, it is clear that such a mechanism would succeed if an appropriate cost model were set up with it. Otherwise, users would request the maximum possible QoS.

In WATM, soft QoS control allows effective support of mobile applications with high network capacity utilization. When congestion occurs in WATM, the soft QoS mechanism can allocate bandwidth to connections based on their profiles. The ITU-TQ 2963 allows three parameters—PCR, SCR, and MBS—to be modified during a call; the modifications allowed are *increase all* or *decrease all*. In addition, traffic parameter modification is done to point-to-point connections and may be requested only by the terminals that initiated the connection setup. An example of a soft QoS control mechanism is implemented by WATMnet, which uses the following modification to the Q2963 signaling mechanism:

- *Bandwidth change indication*: this message is generated by the network or called user to initiate a modification procedure.
- *Modify request*: this message allows the specification of softness profile and associated minimum acceptable satisfaction level.

- *Modify reject*: this message allows the specification of available bandwidth fraction (ABF) for each traffic descriptor parameter (PCR, SCR, and MBS); ABF is defined as the ratio of the available to requested traffic descriptor parameter (ABF-PCR, ABF-SCR, and ABF-MBS).

MOBILITY MANAGEMENT

The ATM standards are designed to support users at fixed locations and do not provide any support for location search and registration transactions that are required by mobile users. They also do not support handoff and re-routing functions that are used to keep the mobile user connected to the network during mobility.

Location Management

Location management is a two-step process that enables the WATM network to discover the current AP of the mobile user for call delivery. The first step is the location registration (or location update). During this step, the mobile terminal periodically notifies the network of its new AP, allowing the network to authenticate the user and revise the user location profile. The second step is the call delivery, during which the network is queried for the user location, and the current position of the mobile host is retrieved. Current techniques for location management involve database architecture design and the transmission of signaling messages among various components of the signaling network. As the number of mobile terminals increases, improved schemes are needed to efficiently support updates, querying delays, and paging methods. Many of the issues involved in the location management are not protocol dependent and can be relevant to different networks.

Mobility management in WATM deals with transitioning from ATM cell transport based upon widely available resources over wireline to cell transport based upon the limited and relatively unreliable resources over the wireless. Therefore, it requires the investigation of important issues such as latency, message delivery, connection routing, and QoS provision. Through the WATM Working Group, the ATM Forum has focused its efforts on developing basic mechanisms and protocol extensions for location management that address these issues. It mainly specified that new procedures must be compatible with the current ATM standards in order to be implemented with relative ease.

Major proposed protocols for WATM implement location management using two classes of techniques: a) location servers, which refer to the use of databases to store and retrieve records of the current positions (AP) of the mobile terminals within the network; and b) location advertisement, which avoids the use of databases by passing location information throughout the network via broadcast messages.

Location Servers

Location servers use two major techniques: the two-tier database and the location registers.

Two-tier database (TTD). The architecture for the TTD scheme uses bi-level databases that are distributed to

zones through the network. Each mobile terminal is assumed to belong to a zone called its *home zone*. Each zone is maintained by a zone maintainer, who is in charge of controlling the zone's location update procedures. The home tier (or HLR) of the zone's database stores location information related to the mobile terminals that are permanently registered within that zone, while the second tier (or VLR) stores location information related to the mobile terminals that are visiting the zone. Upon entering a new zone, the mobile terminal detects the new zone identity broadcast from the BSs. The major steps for registration in the new zone are as follows (Akyol and Cox 1996):

1. The MT transmits a registration request message to the new MSCP that contains its user identification number, authentication data, and the identity of the previous zone.
2. The current MSCP determines the home zone of the MT from the previous zone.
3. The current and home MSCPs authenticate the user and update the home user profile with the new location information.
4. The home zone sends a copy of the profile to the current zone, which stores the profile in the VLR tier of its database.
5. The current MSCP sends a purge message to the previous zone to delete the user's profile from the previous zone's VLR tier.

Call delivery is achieved by routing the call to the last zone first. If the mobile terminal has moved and has been deleted, the call is immediately forwarded to the home zone. The home zone's HLR is queried for the current location of the mobile terminal, which is forwarded back to the calling switch; the connection can be set up to the current serving switch of the mobile terminal.

Location registers hierarchy (LRH). The LRH scheme distributes location servers throughout a hierarchical PNNI architecture. The PNNI procedure is based on a hierarchy of peer groups, each consisting of a collection of ATM switches. Each collection has a special switch called *peer leader group*, which is connected to all of the switches in its peer group. The peer group leader is also connected to a higher-ranking leader in the parent peer group. Each peer group has its own database (or location register) to store location information on every mobile terminal serviced by the peer group (Veeraraghavan and Dommetry 1997). The PNNI hierarchy allows the WATM to route connections to the mobile terminal without requiring the parent nodes to have exact locations—only the lowest referenced peer must record the location. When a mobile terminal executes a location update by sending a registration notification message to the new BS, this message is relayed to the serving switch. The registration procedure is performed as follows:

1. The new switch stores the MT new location information in the peer group's location register (LR).
2. The peer group then relays the new location information to the higher-level LRs for routing needs, stopping

at the first common ancestor (or S-level) of the former and current peer groups.

3. The MT's home LR is then notified of the new S-level location of the MT.
4. After the updates are completed, the new switch sends a message to the previous switch so that the former location can be deleted from the LRs.

For call delivery, an incoming call request can be routed to the last known peer group or switch via the S-level LR. If the mobile has been removed, the last known switch propagates a location request, querying the upstream LRs until the mobile end point's address is recognized by an LR that has a pointer to the mobile current position. Then the request is sent appropriately and the location information is sent back to the calling switch.

The TTD scheme has an advantage over the LRH in that it keeps the number of queries relatively low, requiring at most two look-ups for each incoming call to find the called MT. However, the use of centralized home LR may cause increased signaling traffic and unnecessary connection setup delays if the MT is highly mobile. On the other hand, LRH has the advantage of providing information that conforms to the routing protocol in the wireline part of the network. Finally, although the two methods provide the advantage of simplicity and flexibility, they require a considerable signaling and database querying load.

Location Advertisement

Location advertisement aims to reduce the signaling and database querying load. WATM advertisement refers to the notification of appropriate network nodes of the current location of mobile terminals. Three methods can be used for location advertisement: a) the mobile PNNI, which uses the PNNI architecture by taking advantage of the internal broadcast mechanism; b) the destination-routed virtual connection trees, which advertise location information via provisioned virtual paths; and c) the integrated location resolution, which extends the signaling framework of ATM with location information elements (Akyildiz et al. 1999).

Mobile PNNI. This method uses the status notification procedures of the PNNI network to achieve automatic registration, tracing, and location of mobile terminals. The PNNI protocol calls for the exchange of PNNI topology state packets (PTSPs) between the ATM switches. The PTSPs are generated by the peer group leaders and contain information about the topology of the group, the load of each peer switch, and reachability information (i.e., address and parent peer group). By using PNNI, location information for each mobile terminal can be propagated through the WATM network. The registration procedure takes place without the use of a database and simply includes the location information in these PTSP packets. A mobile is assigned to a home switch, which is in charge of storing the route to the mobile's current switch location. The routing table is updated whenever the mobile accesses the network, leaves it, or moves to a new switch (Veeraraghavan and Dommetry 1997).

The registration procedures can be implemented via two steps: 1) the MT sends a registration message to the home switch; and 2) the home switch and the current peer group leader propagate the new location information using the PTSPs. The extended mobile PNNI algorithm includes a scheme to flood the exact location of the mobile terminal through a region of the network called a *neighborhood*. If the mobile moves to a new switch in the neighborhood of its home switch, the exact location will be flooded to the home switch, and switches outside the neighborhood will only receive the default information. When the mobile moves to a new switch, located out of the home neighborhood, the mobile must register its new location with the home switch. In both cases, the previous switch must be notified.

The call delivery can be immediately routed to the correct switch when the call is generated from inside the same neighborhood or from the home neighborhood. In all other situations, the home switch has to route the call to the current switch. However, if the latest reachability update has not been propagated completely, the last known switch has the responsibility to forward the call to the current switch.

Destination-routed virtual connection trees. This method considers that the network architecture is a collection of portable BSs connected via provisioned virtual paths that constitute a connection tree. The portable BSs are equipped with switching and buffering capabilities. Each portable BS maintains a running list of resident mobiles in its coverage. When the mobile registers or deregisters, it sends a message to its current portable BS, which adds the mobile to (or deletes the mobile from) the service list. In addition, when the mobile moves into the portable BS's region, the new portable BS must send a deregistration message to the old portable BS on behalf of the mobile and stores the mobile's identity information in its list.

Call delivery is performed by advertising the mobile terminal's identity using a broadcast message from the portable BS of the calling mobile entity. The current portable BS responds to the broadcast and starts the connection procedure. If there is no response, the connection is rejected.

Integrated location resolution (ILR). This method modifies the signaling related to the ATM call setup process to add indications of the called mobile terminal's current location. In ILR, the mobile terminal is allocated to a switch that manages information related to mobile location. When the mobile terminal moves to a new switch, it registers its presence with the new switch. The new switch is in charge of notifying the mobile's home switch of the mobile's new foreign address.

Initial call requests are routed immediately to the called mobile terminal's home switch along with a connection setup message. The call delivery for a mobile terminal that is currently away from its home switch is implemented as follows:

1. The calling terminal issues a connection setup message to the MT's home switch, which first determines that the mobile is away from home.
2. The MT's home switch sends a release message to the originating switch. This message indicates the MT's current foreign address and identifies the connection as mobile.
3. A switch in the original setup path establishes a new path for the connection to the MT and sends a new setup message to the MT's foreign address, which includes the MT's home address.

Handover Management

WATM is responsible for routing traffic through the wireless network to the wireless access point, which is currently in charge of the radio communication with the mobile terminal under its coverage. When the mobile terminal moves to a new cell covered by another AP, the WATM system must reroute traffic to the new AP for delivery. To provide communication continuity, the network must apply mechanisms responsible for handoff management, which enables WATM to maintain a user's connection at a certain level of QoS as the mobile terminal moves and changes its access point to WATM.

Typically, a handoff involves a three-step process: 1) the initiation step, during which an entity (the user or the operator) identifies the need for handoff; 2) the new connection generation, during which the network has to assign resources for the handoff connection and perform any additional routing operations; and 3) the data flow control, in which the delivery of data from the old connection path to the new connection path is maintained. In general, a handoff is one of two types: intracell handoff or intercell handoff. Intracell handoff occurs when the user moves within a cell and experiences signal strength deterioration below an acceptable threshold that results in the transfer of the user's calls to new radio channels of appropriate strength at the same base station. Intercell handoff occurs when the user moves to an adjacent cell and all its connections must be transferred to the new AP.

The main issue during handover in a WATM environment is to reduce disconnection and preserve connection quality. The requirements for the handover procedure are expanded and detailed in ATM Forum/97-0153 (Porter et al. 1996). The major requirements can be defined as follows:

- The handover procedure should be global, in the sense that it must support handover between: 1) APs within a private network; 2) APs occurring in different private networks connected by a public network; and 3) APs belonging to public networks (ATM core).
- The switching of the active virtual channels from the old routing path to the new routing path should be efficiently performed in order to minimize the interruption to cell transport.
- The handover process should be performed sufficiently fast, so that the handover decision is still valid for the new position of the mobile terminal after the handover process is complete. In fact, ensuring the completion of handover with very low delay is of primary importance in WATM.
- The handover procedure should preserve the contracted QoS of all virtual channels affected by the handover.

When this cannot be satisfied, a renegotiation process or a selective dropping process should be implemented (the dropping can be made on a priority based, if needed).

- The handover procedure should minimize the probability of cell loss while avoiding cell duplication and reordering.

The function of the handover procedure is to guarantee user mobility among the access points of the mobile ATM with no degradation of the QoS requirements. Four categories of protocols for handoff can be considered: 1) Route augmentation, which extends the original connection via a hop to the mobile's next location; 2) full connection rerouting, which maintains the connection by establishing a new route for each handoff as if it is a new call; 3) partial connection rerouting, which reestablishes some segments of the original connection while preserving the remaining ones; and 4) multicast connection rerouting, which combines the first three techniques and includes the maintenance of handoff connection routes to support the original connection.

Route Augmentation

This scheme provides a level of speed and simplicity that can potentially reduce the handoff latency and signaling complexity. It aims to extend the route of a connection from the old AP of a mobile terminal—for example, AP1—to its current switch, denoted by AP2. The key issue behind this scheme is that, following handover, the new connection consists of the existing connection from the source to AP1 followed by an additional subpath (referred to as an “extension”) from AP1 to AP2. The first clear advantage of this scheme is that it makes it easier to implement handoff without affecting cell order during the handover procedure. However, the path extension simply increases the end-to-end delay and reduces network utilization because it increases the average number of paths. It also may create loops (because the new path may traverse the old path). A simple optimization of this scheme can be used to detect and eliminate loops.

Full Connection Rerouting

This scheme is the most optimal and simplest rerouting technique. It involves changing all of the segments in the connection path from the source to the previous switch. Then new channels are established from the source to the new switch, which is done by considering the connection a newly admitted call. The procedure involved in the full connection reroute handoff is outlined as follows: after registration, the mobile terminal informs the target switch of the identity of the original connection. Then the target switch forwards the handoff request to the calling switch. The calling switch and the target switch set up a new connection to the mobile terminal. Finally, to clear the original path, the calling switch sends a clear message along the old path toward the old switch.

Partial Connection Rerouting

This scheme attempts to route a connection by preserving some segments of the original route for resource

management and simplicity. Two algorithms can be used for this scheme: the nearest common node rerouting (NCNR) algorithm and the hybrid connection algorithm (HCA). The NCNR routes connections according to the concept of zone. Handoff within a zone constitutes a VC update, whereas handoff between zones is based on an attempt of the algorithm to bridge the connection at the nearest WATM network node that is common to both of the zones involved in the handoff transaction. The common node can be defined as follows: in a tree topology, the common node refers to the lowest node (in the tree) that is an ancestor of the two zones. In a hierarchy structure, the common node is a higher switch that uses separate paths to the zones.

An HCA protocol starts with the mobile terminal moving to an overlapping cluster, which is a collection of BSs connected to a common cluster switch. The target BS should determine whether the handoff is intracluster or intercluster. If the handoff is intracluster, the cluster switch can perform as a crossover switch (COS); otherwise, a COS discovery process must be executed. By the time the mobile terminal fully enters the new cluster, the new path is established and the mobile terminal can send a message to the target, which can send a redirect to the COS to become part of the new connection path. Finally, the COS informs the old BS to disconnect the old path.

Multicast Connection Rerouting

This scheme combines the different paradigms presented in the preceding handoff protocols and introduces the concept of maintaining potential handoff connections in addition to the original connection. During a handoff, little network time is spent selecting a new route because several routes are already available. Two algorithms typically are used for multicast rerouting: the virtual connection tree (VCT) algorithm and the homing algorithm (HA). The VCT algorithm is based on a hierarchical collection of switching nodes connected to an ATM network in which the root is a fixed switch. Each mobile connection is assigned a set of virtual connection numbers (VCNs) that are used to identify a set of paths from the root to a leaf on the tree. The algorithm assumes that only one path is operational at a time, and that a call can be generated by a mobile terminal attached to a leaf and then sent through the root.

Handover QoS

A key issue that must be taken into account during the handover process is that of minimizing the effects of QoS disruption; handover blocking as a result of limited resources at target APs, cell loss during handover; or the speed of the whole handover process are some of the critical factors for QoS. One way to minimize QoS disruption during handover is to ensure a lossless handover. In a network consisting of very small radio cells, the number of handovers may be high—if even a single ATM cell is lost at each handover, the overall effect of cell loss on the system throughput could be significant (with the experience of delay as well). Therefore, a key design aim of handover is to be lossless.

To ensure a lossless handover, all cells in transit during the handover procedure are buffered within the network in order to maintain in-sequence cell delivery, without loss, to the wireless mobile terminal. However, ensuring lossless operation is typically done at the expense of introducing additional buffering and, therefore, a delay. This delay needs to be minimized. Hence, an issue to be further investigated is the planning of a lossless handover mechanism that also features low delay and delay variation.

An important issue in WATM that needs further investigation is the planning of an optimal handover procedure that provides the network a guaranteed level of QoS that is protected against cell loss, cell duplication, and loss of cell sequence. An optimal design of handover should offer a lossless mechanism with low delay and delay variation. It is important, in the design of handover, to have in mind some critical factors that influence handover QoS; these include handover blocking due to limited resources at target APs, cell loss during handover, and the speed of the whole handover process.

Implementing handover by choosing the right scheme and type must ensure enhanced QoS for the connection as well as handover reliability. The main consideration during handover is to maintain connection quality. Ensuring the completion of the handover procedure by preventing any cell loss and avoiding cell duplication or cell reordering with very low delay is of primary importance. Hence, a major subject for WATM research is the development of solutions ensuring that QoS resources keep pace with continually changing network states (resulting from user mobility) without consuming large amounts of overhead in the process.

WATM STANDARDS AND IMPLEMENTATIONS

WATM standards have been described by the ATM Forum (Bautz 1997; Deane 1996). The benefits that ATM provides to transport networking standards will need to be extended to support wireless networking. This extension will be developed in private wireless networks as well as public networks. The WATM-WG was specified to facilitate the integration of ATM technology to wireless networks, including cellular, fixed wireless, ad hoc networking, and satellite networks.

First, the ATM forum has developed a specification for micro cellular-based systems. This specification includes mobile ATM extensions to support mobility within an ATM network. The WATM specifications are used in networks involving terminal mobility or radio access and are designed for compatibility with standard ATM equipment. These specifications concern the radio access protocols, which include radio physical layer MAC for wireless channels, DLC for wireless channels errors, and wireless control protocol for radio resource management protocol extension. They also include control of location management for mobile terminals, routing for mobile connections traffic/QoS control for mobile connections, and wireless network management. The radio access specifications are dependent on the radio access technology and frequency.

The enterprises NEC, ORL, NTT, and Lucent Technologies have developed many experimental mobile ATM testbeds. A prototype called the seamless WATM network (SWAN) is an experimental indoor WATM network based on off-the-shelf 2.4 GHz ISM band radios that operate at 625 Kbps between the base and mobile terminal; it investigates the combination of wireless access and multimedia networked computing. SWAN uses room-sized pico cells and mobile multimedia end points. It enables users carrying multimedia end points such as personal digital assistants (PDAs), laptops, and portable multimedia terminals to seamlessly roam while accessing multimedia data resident in a backbone wired network. The network model of SWAN consists of BSs connected by a wired ATM backbone network, and WATM last hops to the mobile hosts (Agrawal et al. 1996).

A first-generation (1G) radio ATM testbed (Porter et al. 1996) from Olivetti and Oracle Research (ORL) Laboratories operates at 10 Mbps using a QPSK radio at 2.45 GHz and mobile-capable ORL ATM switches. Slotted ALOHA with exponential backoff is employed at the MAC layer using header compression and support for CRC and ARQ for error control. The next version of this testbed will have a data rate of 25 Mbps (Porter et al. 1996), operate in the 5 GHz bands, and have a range up to 30m instead of the current 10m (Sfikas, Apostolas, and Tafazolli 1998; Yuan and Motoyama 2002).

The radio ATM prototype is presented as a solution to the problem of connectivity of portables to an ATM wired network in the in-building environment. It is based on a picocellular system with a large number of BSs designed to be deployed in large numbers, each covering a short range with partially overlapping coverages. This increases the aggregate throughput and reduces some of the problems specific to a radio physical layer. Using this approach, the MAC layer is optimized to provide efficient use of bandwidth and support guarantees for ATM traffic classes.

Magic WAND is one of the largest research areas of the European Advanced Communication Technologies and Services (ACTS), working in the field of wireless broadband access networks. The main objective of the project is to design and implement a high-speed indoor WATM network. WAND is a program that is specified for the entire network, from the radio modem to the application layer. Its output is a complete system specification and a technology demonstrator. Furthermore, a set of applications—including video conference and multimedia software—is developed for the system verification. The usability and performance of the WAND system has been evaluated during the public user trials conducted in Finland and in Germany in 1998. The evaluation demonstrated the technical feasibility and business viability of a wireless media for the distribution of advanced multimedia products.

CONCLUSION

ATM is currently used in private LANs, cable TV, data networks, backbones for long-distance services, and digital subscriber line (DSL) systems for broadband residential and business services. Wireless ATM equipment and mobile products still are provisional and unproven. There are no industry-wide standards in place for implementations

in either fixed or mobile environments. Solutions that do exist are proprietary, and numerous critics say that ATM's validity remains questionable in the mobile environment (Bautz 1997). However, according to some industry observers, the integration of ATM in wireless environments is promising because wireless networks already tend toward more speed and diversity.

Moreover, ATM allows the QoS provision of diverse types of applications and presents a successful way to manage delay in a wireless broadband network. This protocol has become a common option among fixed wireless service providers. On the carrier level, ATM has established itself and should continue to consolidate its position as the protocol of choice for high-capacity fiber pipes. However, whether ATM will successfully extend its reach into last-mile applications remains doubtful (Bautz 1997).

Some believe that the high multipath resistance and soft handovers associated with CDMA would provide an attractive environment for integrating ATM to wireless environments, but other research has suggested that the combination would not be efficient. Rather, ATM is best suited to TDMA schemes in which cell length and time slots can coincide, and each cell can occupy a single time slot. It is perhaps for this reason that companies have looked more favorably on third-generation implementations of ATM. In any case, high data losses appear to be a given in wireless ATM mobile networks, and powerful error correction combined with dynamic negotiation schemes may be the only way to make mobile ATM work (Hakan 1995). Despite the advantages and promises of WATM, its implementation seems to be expensive for operators compared with other candidates.

GLOSSARY

AAL (ATM Adaptation Layer): Used to adapt the protocol data units (PDUs) passed down from the higher layer to ATM cells. As the higher-level PDUs may have, in general, an arbitrary size, two functions are provided by the AAL: a) the segmentation and reassembly, and b) the convergence, which is responsible for packaging the higher-layer PDU with any additional information required for adaptation.

ATM (Asynchronous Transfer Mode): A dedicated-connection switching technology that organizes digital data into 53-byte cell units and transmits them over a physical medium using digital signal technology.

ATM Cell: The basic unit of information transfer in the ATM communication. The cell has a length of 53 bytes: five of the bytes make up the header field and the remaining 48 bytes form the user information field.

ATM QoS: The measurement, improvement, and guarantee in advance of transmission cells, error rates, and other characteristics controlled by ATM. QoS is of particular concern for the continuous transmission of high-bandwidth services. QoS is handled by ATM on the basis of service contract.

ATM Services: Four basic services are provided by the ATM. They are: 1) the constant bit rate (CBR), which specifies a fixed bit rate so that data are sent in a stream; 2) the variable bit rate (VBR), which provides a specified throughput capacity, though data are not

sent evenly (this is a popular choice for voice and videoconferencing data); 3) the available bit rate (ABR), which provides a guaranteed minimum capacity but allows data to be bursted at higher capacities when the network is free; and 4) the unspecified bit rate (UBR), which does not guarantee any throughput levels (this is used for applications, such as file transfer, that can tolerate delays).

Handover: In a cellular telephone network, the transition of any given user of signal transmission from one base station to a geographically adjacent base station as the user moves around.

Q.2931+: An ITU signaling protocol that specifies the procedures for the establishment, maintenance, and clearing of network connections at the user network interface. The procedures are defined in terms of messages exchanged.

WAND: Magic WAND is a joint European project to develop a demonstration of mobile terminals for multimedia information access using a fast and wireless ATM network. Communication between the mobiles is based on portable computers, and the access points serviced by an ATM switch take place in the 5 GHz range.

INTRODUCTION

Internet protocol (IP) telephony or *voice over IP (VoIP)* has seen tremendous growth in the past few years and is predicted to grow rapidly in the coming years. For instance, according to the Web site ZDNet, total VoIP equipment revenue will rise some threefold to \$11.9 billion by 2010 from \$3.95 billion in 2005. Both business and residential customers are switching to IP telephony. The main attractions of IP telephony are (1) cost savings, (2) better resource utilization, (3) numerous compelling services and applications arising from wireless IP telephony and its integration with Internet-based applications, and (4) reduced network administration and management.

Similarly, *wireless local area network (WLAN)* technologies, mainly *wireless fidelity (WiFi)*, have grown rapidly and are becoming ubiquitous. Considering the popularity of these two important technologies (namely, IP telephony and wireless LAN), wireless IP telephony has emerged as an attractive combination that reduces costs, increases access, and provides greater control over enhanced enterprise communications tools. Current literature shows that significant savings are realized with VoIP using WiFi: Cellular phone roaming at \$1.25 per minute, for instance, can be reduced to \$0.02 per minute using wireless IP telephony. In fact, “dual-mode” phones such as Nokia N80 and Motorola A910 that support both cellular and wireless IP telephony are available now. This allows organizations to save on cellular phone expenses as employees use IP telephony over wireless LAN when located on company premises. Furthermore, cellular networks and WiFi complement each other in their data-transfer rates and coverage areas. Although WiFi can support high data rates (currently, as high as 54 Mbps), cellular networks support only a maximum data rate of a few Mbps. However, cellular networks have especially good geographical coverage unlike WiFi, which is only available in limited areas (sometimes referred to as *hot spots*). In addition, cellular networks typically do not have good coverage inside buildings, and in such cases wireless IP telephony can provide better connectivity and voice quality.

There are a number of technological challenges associated with transporting real-time data such as voice and

video over wireless. In this chapter, we will discuss the state of the art of wireless IP telephony. In particular, we will discuss issues related to (1) mobility management; (2) *quality of service (QoS)*, including mechanisms for call admission control; (3) security and privacy; and (4) *enhanced 911 (E911)*. Because 802.11 (IEEE 1999) (or WiFi) is the most popular WLAN technology, we discuss most of these issues in the context of 802.11-based standards, which are briefly described below.

802.11 Standards

The most commonly used WLAN technology is based on the 802.11 (or WiFi) standards (IEEE 1999). This umbrella encompasses various formalized standards that define different aspects of the WiFi technology. The WiFi physical layer is defined by standards such as 802.11b (11 Mbps) and 802.11g (54 Mbps). The forthcoming 802.11n standard, which is now in the draft stage, aims to increase data throughputs to as much as 600 Mbps.

In addition to letter standards that specify data rates, other 802.11 standards relevant to wireless IP telephony are:

- 802.11i, which defines security mechanism such as authentication, encryption, and access control;
- 802.11e, which provides QoS support for real-time applications such as voice and video; and
- 802.11r (not approved yet), which aims to reduce hand-off latency during transitions between access points such that time-sensitive applications such as IP telephony are not disrupted.

For a more detailed description of 802.11 standards, see the chapter “Wireless LANs (WLANs).”

Devices using 802.11 have two modes of operation: (1) ad hoc, in which the devices directly communicate with each other, and (2) infrastructure, in which the 802.11 devices communicate through an access point.

In the infrastructure mode, an 802.11 system consists of *stations (STAs)* and *access points (APs)* as shown in

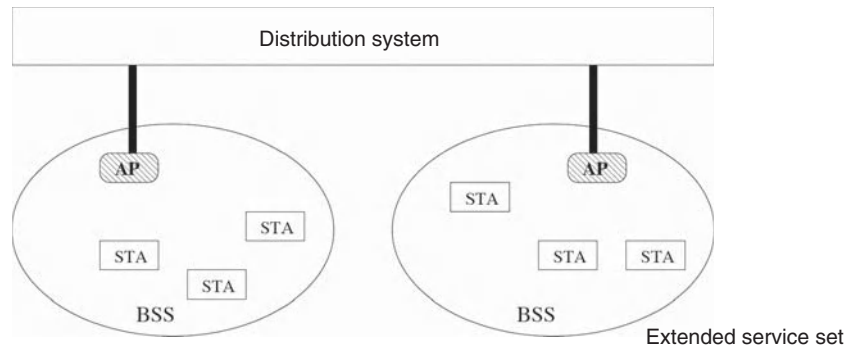

Figure 1: 802.11 infrastructure-mode architecture

Figure 1. One AP and multiple STAs that receive service from that AP constitute a *basic service set* (BSS). Multiple BSSs connected through a wired network, such as a LAN, are referred to as an *extended service set*.

Because most 802.11 installations use infrastructure mode, in the rest of this chapter, we will assume that a 802.11 network operates in this mode (unless stated otherwise).

WiMAX and IP Telephony

WiMAX (802.16) is an upcoming standard for broadband wireless wide area network access. It has a range of approximately 6 miles radius and speeds of as high as 40 Mbps per channel. The initial version of WiMAX (also called *fixed WiMAX*) is aimed at stationary or nonmobile applications, which are not sensitive to longer handoff times; a later version (802.16e or *mobile WiMAX*) aims to provide support for mobility and real-time applications such as IP telephony. For further information on WiMAX, see the chapter “Wireless Wide Area Networks (WWANs).”

Organization

The rest of this chapter is organized into five sections: mobility management; quality of service issues; security and privacy; enhanced 911; and, lastly, a conclusion.

MOBILITY MANAGEMENT

For IP telephony over wireless, mobility management has to be addressed at various levels. Standards set forth by the International Telecommunications Union (ITU) (see ITU-T 2003) recommend that for real-time voice communication, the one-way delay should be less than 150 ms. Latencies greater than this value result in poor voice quality and are discernible by a user. Handoffs between wireless APs must be done in a fast and seamless manner so that existing calls are not disrupted. In addition to L2 (layer 2, the data link layer) mobility, L3 (layer 3, the network layer) mobility is also important because the user could move to a different wireless subnet or network. Again, this must be done without any service disruption. Various mobility management techniques are discussed in

Sharma, Zhu, and Chiueh 2004; Dutta et al. 2002; Ramani and Savage 2005; Mishra, Shin, and Arbaugh 2004; Park et al. 2004; Pack and Choi 2002.

Layer 2 Mobility

WiFi clients receive service through APs that typically provide coverage to distances up to 100 meters from an AP. Thus, a person using a WiFi-enabled device for a VoIP call could traverse the coverage area of several APs while walking from one area of a building to another. Furthermore, at any time, a WiFi device can only be associated with one AP (this limitation, which is part of the WiFi standards, enables packets to be efficiently routed to a WiFi device).

The process involved in changing the association from one AP to another is called a *handoff* or *handover*. A handoff usually occurs when a device moves out of the range of its current AP, causing its signal strength or signal-to-noise ratio to become unacceptable. Handoffs can be *hard* or *soft*. In a soft handoff, also referred to as a *make-before-break* handoff, the device first establishes connection with the new point of attachment before breaking the existing connection. This results in a more seamless handoff as compared to a hard handoff, also called a *break-before-make* handoff, in which the connection with the existing attachment point is broken before the new one is established.

Handoffs routinely happen during a call in cellular networks. There are two main reasons why handoffs in a cellular network are much smoother as compared to WiFi (Ramani and Savage 2005). First, in 802.11, the clients manage a handoff autonomously and independently without any knowledge of the network topology or other network characteristics. In cellular networks, by contrast, a *base station controller* or a *mobile switching center* initiates a handoff with full knowledge of the local topology and conditions such as the number of clients in the area. Furthermore, in cellular networks such as *code division multiple access* (CDMA) (Viterbi 1995), the phones perform a soft handoff in which the phone simultaneously communicates with multiple *base transceiver stations* (BTSs) before the handoff is executed to one of them. In 802.11, a handoff is hard.

Second, in cellular networks, a client continuously measures its connectivity with all the BTSs within its

range and assists the network in choosing the best alternative. However, in 802.11, a client only measures the quality of its current channel because it can only send and receive on a single channel at a time. When this quality goes below a threshold, the client switches to other channels to explore the possibility of a handoff to an AP with acceptable quality. (Note that while this switchover is in progress, frames on the current channel are dropped.) There is a trade-off involved in setting this voice quality threshold value. If it is too high, it is possible that the client does not find any other AP with better quality and thus unnecessarily causes a “gap” in the service because of the search for other APs. On the other hand, if the threshold is too low, the client may continue to be attached to an AP with poor signal quality even when a better quality AP is available. Unlike the cellular network, the time taken to perform handoffs in 802.11 networks is high, ranging from several hundred milliseconds to a second, which is unsuitable for real-time traffic such as voice.

The 802.11 standard provides excellent support for “portable” entities—that is, entities that migrate frequently but do not have strict connectivity requirements while they are in motion. However, because of the handoff mechanism used and the high handoff latency, 802.11 does not provide much support for “mobile” entities—that is, entities that have tight latency and response time requirements while they are in motion. We now provide a brief description of the L2 handoff process. This is followed by a discussion of the recent research aimed at improving the L2 handoff latency.

L2 Handoff

A handoff is required as a station moves from one BSS to another. It is critical that the time taken for a handoff, or, the handoff latency, is minimal. As mentioned earlier, this latency should ideally be less than 150 ms. For seamless service, it is important that the handoff is done at the right time and to the right AP.

The steps involved in a handoff are described below and shown in Figure 2. It consists of three main phases: (1) discovery, (2) reauthentication, and, (3) reassociation.

Discovery. The discovery phase is entered when the signal quality on the current channel has degraded below a threshold level. The goal of this phase is to find another AP with acceptable signal quality. Depending on the version of 802.11 that the client is running, it switches to the corresponding channel frequencies one at a time. For each channel, the client either (1) waits for the periodic beacon (which is usually sent by an AP every 100 ms) in order to measure the quality of the corresponding AP’s channel (*passive probing*) or (2) actively broadcasts a probe on the channel so that an AP operating in that channel replies back (*active probing*). Normally, active probing is much faster than passive probing.

The time taken by active probing is as follows (Ramani and Savage 2005):

$$\sum_{c=1}^{c=NumChannels} (1 - P(c)).MinChannelTime + P(c).MaxChannelTime$$

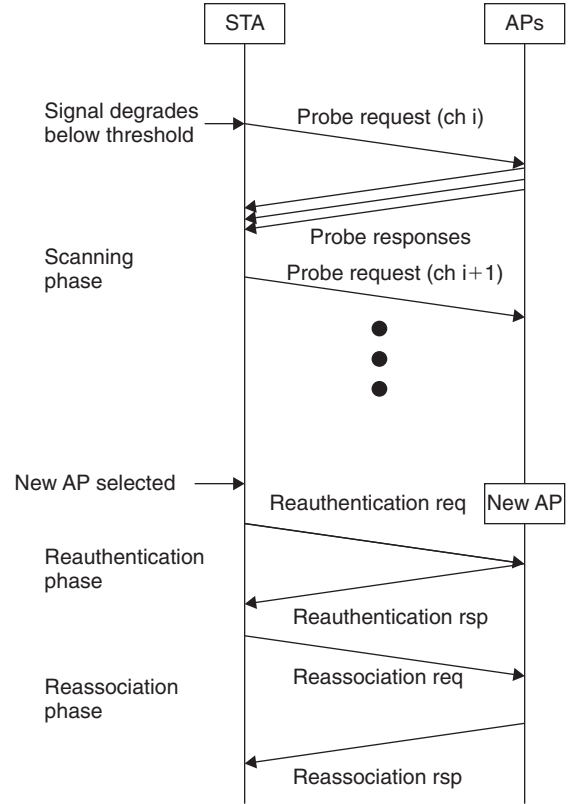

Figure 2: 802.11 handoff phases

where $P(c)$ is the probability that an AP operates in channel c , $MinChannelTime$ is the time the client waits if there is no AP operating in channel c (in other words, if it receives no response at all), and $MaxChannelTime$ is the time the client waits if it receives at least one response (in order to allow other APs operating in that channel to respond). Suggested values of $MinChannelTime$ vary from 1 ms (Velayos and Karlsson 2004) to 7 ms (Mishra, Shin, and Arbaugh 2003), whereas those of $MaxChannelTime$ are approximately 11 ms (Velayos and Karlsson 2004; Mishra, Shin, and Arbaugh 2003). Using an average value of 4 ms for $MinChannelTime$ and 11 ms for $MaxChannelTime$, and assuming eleven total channels (as is the case in 802.11b/g) gives the probing latency of from 40 ms (if no other AP is found) to 110 ms (if at least one AP is found on each channel). In addition, *channel switching delay* is incurred whenever a channel is changed. This can add a substantial amount of delay to the probing process. Ramani and Savage (2005) find that the probing delay using active probing for a popular 802.11b network interface card to be between 350 ms and 400 ms.

Reauthentication. After a new AP is selected, the client exchanges authentication messages with it. These establish the client’s identity and its permission to use that particular AP. The reauthentication delay is approximately 20 ms (Mishra, Shin, and Arbaugh 2004).

Reassociation. After authentication, the client sends a reassociation request to the new AP, expecting a reassociation response in return to finalize the handoff. When an

AP receives a reassociation request, it exchanges station context information with the client's earlier AP. Interaccess point protocol or 802.11f is used for this exchange. The reassociation delay is on the order of approximately 20 ms.

The total time taken by the handoff process, which is the sum of the three phases, is approximately 500 ms to 1 sec (Ramani and Savage 2005). Furthermore, the probing delay is roughly 90 percent of the total time taken (Mishra, Shin, and Arbaugh 2003).

Improving L2 Handoff Latency

An extensive body of research exists on enabling faster layer 2 handoffs in order to make WLANs more suitable for IP telephony (Ramani and Savage 2005; Brik, Mishra, and Banerjee 2005; Velayos and Karlsson 2004; Mishra, Shin, and Arbaugh 2004; Park et al. 2004; Shin et al. 2004; Pack and Choi 2002). Research aimed at reducing the time taken for each of the three phases of the handoff is presented in these papers. However, because the discovery phase takes almost 90 percent of the total handoff time, a number of researchers have suggested techniques to reduce the time taken for this phase.

In SyncScan (Ramani and Savage 2005), the authors propose synchronizing the clocks on the APs and the mobile devices so that the devices can predict the exact time when the periodic beacon from an AP will be sent. This would allow a device to continuously monitor the signals from all of the APs within its range. A concern with this technique is that the device will not be able to send or receive frames on its current channel while it reads beacons on the other channels. In other words, the frames sent or received on the current channel will be dropped during these times. This problem is addressed by using send and receive buffers. Whenever the device is tuned to other channels, the frames are buffered and later processed when the device returns to its current channel. Park et al. (2004) construct a neighbor graph using network topology to narrow the list of channels, and only a few selected channels are probed. Furthermore, the authors propose algorithms that can be used to automatically generate a neighbor graph. Shin et al. (2004) use a combination of selective scanning and caching. In the selective scanning algorithm, the client remembers the channels on which replies were received on previous occasions. This reduces the handoff latency by 30 percent to 60 percent. The caching algorithm maintains a record of previous handoffs. Each entry in the cache table, keyed by an AP, stores as many as two other APs (and their corresponding channels) to which a handoff was performed from that AP. If a handoff needs to be performed, the cache table is checked first. If there is a cache hit and at least one of the two APs is still available, then the client does not need to perform scanning. However, if there is a cache miss, the selective scanning algorithm is used.

In Multiscan (Brik, Mishra, and Banerjee 2005), the authors propose to eliminate handoff latencies through use of additional client hardware. They suggest using two wireless interfaces, one of which is dedicated to looking for alternate APs. This continuous monitoring of the available APs allows the client to seamlessly handoff ongoing connections. Unlike SyncScan, Multiscan only requires changes to the clients; no changes are required to the AP

infrastructure. Furthermore, unlike some techniques, Multiscan does not require any knowledge of the network topology.

In Mishra, Shin, and Arbaugh (2004), the authors aim to reduce the reassociation delay of the handoff process. Network topology information, stored as "neighbor graphs," is used to send the station context information ahead of time to APs adjacent to the client's current AP such that the context information is transferred to an AP before a client performs a handoff to it. Using this technique, the reassociation delay is reduced to 1.69 ms from 15.37 ms in the experiments performed by the authors. Although this is an order of magnitude improvement, it should be noted that the reassociation delay constitutes only a small part of the total handoff delay, and therefore the improvement made to the total handoff latency by this technique is not especially significant.

Pack and Choi (2002) examine ways to reduce the reauthentication delay. They propose to minimize this delay by having a client perform authentication (preauthentication) with multiple APs and not just its current AP.

Layer 3 Mobility

Layer 3 (or network layer) mobility is provided by the use of Mobile IP (Perkins 2002), which is an extension of IP to support mobile applications. It allows an Internet end point to retain its IP address (home address) irrespective of its point of attachment to the Internet. In other words, a host can roam across IP subnets or networks and still is contactable via its home address. This is accomplished by maintaining a home agent, whose location is fixed, and a foreign agent that registers on behalf of a mobile host. When the host is roaming, it additionally acquires a care-of address that is registered with the home agent. The host always uses its home address as the source address in any packet it sends out. The far end responds back to the host home address, which is received by the home agent. The home agent then tunnels it to the host's care-of address (located on the foreign agent). The foreign agent detunnels packets and delivers them to the mobile host. In some situations, to avoid issues with egress filters, the packets sent out by a mobile host may first be tunneled to the home agent and then sent to its intended destination. It should be noted that here the home agent acts much like a proxy for the mobile host.

For wireless IP telephony, Mobile IP allows greater mobility to end-point devices that can seamlessly move between different wireless IP subnets or networks without any disruption to ongoing calls.

Although support for network layer mobility as provided by Mobile IP is necessary for wireless IP telephony to work, it is not sufficient. Because of the strict latency requirements for voice, network layer handoff must be executed fast enough so that ongoing calls are not disrupted. In the context of Mobile IP, network layer handoff would be necessary whenever a mobile host moves to a different subnet or network. This would involve (1) tearing down the old tunnel, (2) acquiring a new care-of address, (3) registering this address with the home agent, and (4) establishing a new tunnel. Sharma, Zhu, and Chiueh (2004) discuss optimization of each of the phases involved in the

handoff and achieve a reduction in the network handoff latency by a factor of 5.

In some extensions of Mobile IP, several care-of addresses can be registered simultaneously. The home agent tunnels the packets to all these addresses. This is particularly useful in a wireless environment in which the host is rapidly changing its point of attachment to the Internet. Mobile IP is supported in IPv6 (Johnson, Perkins, and Arkko 2004) with some enhancements and better integration in the TCP/IP stack as compared to IPv4. Among other advantages (Johnson, Perkins, and Arkko 2004), this obviates the need for a foreign agent. Even after a successful handoff, Mobile IP has drawbacks such as tunneling overhead and triangular routing, which is inefficient especially for delay-sensitive real-time traffic such as voice and video. To address this, Mobile IPv6 supports route optimization that allows a peer to send traffic directly to the care-of address, instead of the home address, of the mobile host (Johnson, Perkins, and Arkko 2004).

Application Layer Mobility

An alternative to supporting mobility management at the network layer is to handle it at the application layer, particularly in view of the inefficiencies incurred by network layer mechanisms such as Mobile IP. *Session initiation protocol* (SIP) can be used for performing a handoff at the application layer. SIP, described in the chapter "Voice over IP (VoIP)" is the most popular and industry accepted protocol for call control in IP telephony.

Each mobile host belongs to a home region where a SIP proxy server provides registrar service. Whenever a host moves to another region, it communicates with the local SIP proxy. Before providing service, the local (visited) proxy authenticates and registers the host with the host's home registrar. When a mobile host on an active call moves from one network to another, the following steps are involved in the handoff:

1. The host acquires a new IP address (e.g., by use of DHCP).
2. The host exchanges a set of messages with the visited SIP proxy for authentication and registration (note that the address of the SIP proxy server is included in the DHCP response).
3. After successful registration, the host sends a re-INVITE SIP message to the peer host using the call identifier of the original call to reestablish the call session. This is also referred to as *midcall mobility*, compared to *precall mobility* in which the host moves when there is no active call.

Because a number of messages need to be exchanged during handoff, the handoff delay can easily exceed 1 sec and thus is not suitable for real-time traffic (Nakajima et al. 2003). Several solutions based on SIP that minimize this delay have been proposed (Wang, Abu-Rgheff, and Akram 2004; Vali et al. 2003; Banerjee, Das, and Acharya 2006; Kwon, Gerla, and Das 2002). In Kwon, Gerla, and Das (2002), the authors propose using *shadow registration*. The key idea is that the host's current region a priori transfers authentication information related to that host to all of

the neighboring regions in anticipation of the host moving to one of them. When the host does move to one of the neighboring regions, the registration step is much faster because the visited SIP registrar does not have to communicate to the host's home registrar. In Banerjee, Das, and Acharya (2006), the authors propose a soft handoff for SIP clients which have multiple network interfaces.

Vertical Handoff

A *vertical handoff* is one between heterogeneous networks—for example, between a cellular network and a WLAN. With the emergence of multimode phones (i.e., with multiple network interfaces), mobile users expect seamless operation and connectivity while moving from one network to another. For example, an employee using cellular service expects her call to seamlessly switch to wireless IP telephony once she is within the range of a WiFi service available on her company premises. A vertical handoff cannot be performed without application-level support. In Wu et al. (2005), a case study is performed of the delay incurred during vertical handoff in a WLAN-universal mobile telephone service (UMTS) internetwork using SIP as the mobility management protocol. The results show that a WLAN-to-UMTS handoff incurs a much larger delay (because of error-prone and bandwidth-limited wireless links) than a UMTS-to-WLAN handoff. It is suggested that soft handoff techniques be used to bring the handoff delay within acceptable limits.

QUALITY-OF-SERVICE ISSUES

Wireless IP telephony must provide same or better call quality as traditional telephony systems. Traditionally, IP (and wireless IP) has been a best effort service with each packet treated equally irrespective of its content. Although this works well for non-real-time applications such as file transfers and e-mail, real-time applications such as voice and video require strict performance guarantees from the network. If packet latency or delay, jitter, and loss exceed acceptable limits, then it has real user impact in terms of poor voice quality and dropped calls.

As real-time applications have become more prevalent on the TCP/IP networks, various QoS mechanisms have emerged. These mechanisms apply to various layers in the network stack. For the wired Ethernet MAC layer, the Institute of Electrical and Electronics Engineers' (IEEE's) 802.1p provides priority tagging. For the network layer, integrated services (Braden 1997) and differentiated services (Nichols 1998) provide QoS support. However, a QoS mechanism for 802.11 MAC had been lacking until 802.11e was approved in 2005.

The original 802.11 MAC defines two coordination functions for accessing the shared media: *distributed coordination function* (DCF) and *point coordination function* (PCF). DCF essentially uses carrier sense and collision avoidance (through use of the 802.11 RTS-CTS mechanism) for coordinating access. PCF provides channel access through polling by a centralized coordinator that usually resides at the AP. It is optional and only available in the infrastructure mode of operation (that is, when all communication to and from a device goes through an AP). Neither DCF nor PCF provides any QoS mechanisms, and all traffic has

the same priority. More detailed descriptions of DCF and PCF are presented elsewhere in this handbook.

Standard 802.11e

To overcome the lack of QoS support in 802.11, 802.11e was proposed. It provides QoS in two ways.

1. *Prioritized QoS.* 802.11e enhances the DCF channel access mechanism to support different priorities for different traffic categories (similar to DiffServ—see Nichols 1998). This enhanced MAC mechanism is called *enhanced DCF*. Before a frame is transmitted, a 802.11e station listens on a channel to determine if it is busy. This channel-sensing interval depends on the priority of the frame to be transmitted. In other words, the lower the priority of the frame, the larger the sensing time. This increases the probability of transmission of higher-priority frames compared to lower-priority frames.
2. *Parameterized QoS.* 802.11e also allows parameterized QoS where an 802.11e station can effectively request a certain bandwidth to be reserved (similar to RSVP—see Braden 1997). This is provided through *enhanced PCF*. It requires a coordinator (called *hybrid coordinator*, HC) that is usually located at the AP. A station may send a *reservation request* to a HC and be allocated a *transmission opportunity* that indicates the duration for which it can transmit (once it gets a chance to transmit).

A detailed description of 802.11e is presented in Mangold et al. (2002). For wireless IP telephony, 802.11e provides two important services. First, it allows voice frames to be treated at a higher priority as compared to non-real-time data frames. Second, it provides a mechanism for implementing call admission control—that is, it allows restrictions (depending on the capacity of the 802.11 network) to be imposed on the total number of voice calls active at any time.

SECURITY AND PRIVACY

Security and privacy are important requirements of any communication network. These requirements become mandatory if the communication network is used for transferring personal or confidential information. Currently, such traditional telephone networks as the *public switched telephone network* (PSTN) provide an acceptable level of security and privacy. This security and privacy support has been achieved from a number of years of use and experience. IP telephony-based networks have introduced several new security and privacy concerns that have not been fully addressed yet (Ransome and Rittinghouse 2005). Combining wireless communications with IP telephony further introduces new caveats and security concerns that do not occur in PSTN or IP telephony-based networks. It is critical that these security and privacy issues are adequately addressed before implementing a widespread deployment of wireless IP telephony.

Unfortunately, as with IP telephony-based networks, the security and privacy concerns of wireless IP telephony have been overshadowed by the increased convenience,

flexibility, cost effectiveness, and other advantages that it provides. Wireless IP telephony faces greater security and privacy risks because of a combination of several factors. These include the use of TCP/IP, the inherent characteristics of the wireless communications medium, and the relatively new protocols that have yet to be fully developed and tested.

Because wireless IP telephony uses IP as the underlying communication protocol, it inherits all of the known and unknown security weaknesses of IP. The issues of security and privacy were not considered when IP was first designed. As a result, many vulnerabilities are well known. For example, by spoofing source IP addresses, an attacker can impersonate a legitimate user and make phone calls disguised as that user. IP networks are common and easily accessible to the attackers. Furthermore, different parts of IP networks are controlled by different entities—for example, different service providers. Enforcing a common set of security protocols over these different parts of the networks is an extremely challenging task.

The wireless communications medium exacerbates the security and privacy challenges of IP telephony. We identify five sources of increased vulnerability resulting from the introduction of the wireless communications medium. First, the wireless communications medium increases the risk of eavesdropping by someone snooping packets over the air. It is relatively straightforward for an attacker to eavesdrop on a wireless communications medium using commonly available, off-the-shelf, and inexpensive equipment. In fact, it is significantly simpler for an attacker to eavesdrop over a wireless communications medium than over a wired communications medium. Thus, the privacy of telephone conversation is greatly jeopardized by incorporating wireless communication.

Second, it is relatively straightforward to launch denial-of-service attacks in the wireless communications medium. It is relatively easy to tap into a wireless communications medium; in the simplest case, an attacker can jam a wireless communications medium by injecting junk information. Of course, this simple attack requires an attacker to expend a large amount of energy. However, several intelligent denial-of-service attacks are well known that exploit specific communication patterns of network- and transport-level protocols. These attacks selectively jam specific control packets of TCP/IP protocols resulting in large number of retransmissions, or they jam for just long enough to interfere with the tail end of an IP packet. Such intelligent attacks require an attacker to expend little energy, and they cause significant damage in service availability.

Third, an attacker can take advantage of the vulnerabilities of the wireless communications medium to inject legitimate packets. This can enable the attacker to make unauthorized telephone calls, impersonate a legitimate telephone user, or even modify the contents of an ongoing telephone conversation. It is difficult to launch such an attack in traditional PSTN networks, but the wireless communications medium makes launching such attacks simpler.

Fourth, the existence of the wireless communications medium makes it easier for an attacker to compromise telephone user databases. Once again, the main reason

for this simplicity is the wide pervasiveness of the wireless communications medium and the ease with which one can tap into this network. This can allow an attacker not only to steal important private information of a telephone user (including name, address, and social security and credit card numbers) but also to modify this information in insidious ways.

Finally, some parts of the radio spectrum are licensed while others are unlicensed. Cellular telephone service uses licensed radio spectrum, whereas WiFi uses unlicensed radio spectrum. As a result of this and because of high Gaussian (white) noise generated by numerous RF-emitting systems (such as APs that may have been placed in close proximity), chances of interference in WiFi are significantly high, thus making the problem of providing security and privacy more difficult.

These security and privacy vulnerabilities associated with the wireless communications medium are quite well known, and in fact have been addressed to some extent in other applications that use the wireless communications medium. As a result, solutions to address the problems of eavesdropping, tampering, and denial-of-service attacks have been developed. The key problem is that these solutions are typically not suitable for wireless IP telephony. This is because either the proposed solutions do not work well in resource-constrained mobile devices that users of wireless IP telephony tend to use or the quality of service issues such as latency, jitter, and packet loss are adversely affected.

Cryptographic algorithms, particularly asymmetric key algorithms, are highly computation-intensive. They require large amounts of memory and consume lots of power. Mobile wireless users typically tend to use relatively small, resource-constrained devices that run on low power. As a result, traditional cryptographic solutions do not work well in such devices. Furthermore, traditional solutions such as firewalls can delay or even block call setups, while computation-intensive encryption and decryption can cause unacceptable latency and jitter.

It is clear that wireless IP telephony brings in significantly higher security and privacy risks that are more than a mere nuisance. It is critical that these security and privacy concerns be addressed adequately before this promising technology is widely used.

ENHANCED 911

As people depend more on IP telephony (in many cases for all of their telephony service needs), it is vital that emergency services can accurately determine the location of a caller in an emergency in a timely manner. In PSTN systems, when a person makes a 911 call, the call is routed to the nearest *public safety answering point* (PSAP). The PSAP receives the caller's phone number and the exact location of the phone from which the call was made. The Federal Communications Commission (FCC) introduced enhanced 911 to allow mobile or cellular phone users to make 911 emergency calls and enable emergency services to locate the geographic position of the caller. This is typically implemented in current cellular telephone networks by using some form of radio location from the cellular

network or a *global positioning system* (GPS) device built into the phone itself.

The packet-switched technology of IP telephony allows a caller to place a call from anywhere, unlike the PSTN in which a phone's physical location is fixed or a cellular network in which a phone's physical location is tied to the radio tower of the cell in which the phone is currently located. IP telephony severely complicates the provision of E911 service. In fact, earlier IP telephones were not integrated with the 911 system at all. However, the FCC has now mandated all IP telephony service providers to provide 911 service, including the E911 feature. There are several complicated technological problems with integrating E911 with IP telephony, and currently most IP telephony service providers only provide an ad hoc solution. For example, some service providers have encouraged their customers to register their locations from which their 911 calls should be routed to the local PSAP. Other service providers are attempting to connect customers to E911 services through the PSTN. The problem here is that the PSTN is controlled by telecom carriers who are their economic competitors.

The key problem associated with providing E911 service in IP telephony is that it is hard for an IP device to figure out its actual geographic location in a dynamic manner. This problem becomes more complicated in the case of wireless IP telephony because not only is a 911 call using a packet-switched network but also the user is mobile. It can be argued that a user is more likely to be within a short distance from a wireless access point with a fixed location. This provides a simple, though not highly accurate, solution for most situations. However, with the advent of wireless broadband services such as WiMAX or newer ad hoc wireless networks that allow an IP device that is several hops away from a wireless access point to be connected, a user can be significantly far away from a wireless access point. Another solution—although a bit expensive—is to install a GPS chip, which periodically transmits location information, in all handsets. This will enable accurate, near real-time user location information to be determined.

Determining the location of a WiFi client only from the RF signal (that is, without using other technologies such as GPS) is being actively researched. Several WLAN localization techniques have been proposed (e.g., Youssef and Agrawala 2005). Many of these use machine learning techniques to model the location of a WiFi client as a function of the properties of the signal (such as signal strength) that it receives. However, they are not always accurate and reliable. In fact, some commercial WLAN localization solutions (e.g., from Ekahau Inc.) have also emerged in the recent years.

CONCLUSION

In this chapter, we have provided a survey of the current state of the art in wireless IP telephony. We discussed key technical challenges that face wireless telephony related to mobility management, quality of service, security, privacy, and E911. Another challenge is seamless vertical handoff that would allow mobility between a WLAN and a cellular network. To be universally accepted, wireless

IP telephony must provide telephony services with the same degree of quality, high availability, and security as traditional circuit-switched telephony systems. To this end, substantial progress has been made in the past few years, and research solutions exist for most technical issues. However, it remains to be seen how fast these will be adopted and realized by industry.

GLOSSARY

802.11 Ad Hoc Mode: In this mode of operation, 802.11 wireless devices can directly communicate with each other without a need for an AP; also referred to as *peer-to-peer mode*.

802.11 Infrastructure Mode: In this mode of operation, 802.11 wireless devices communicate with each other through an AP, which also provides the connectivity of wireless devices to the wired network.

802.11 Standards: 802.11 (or WiFi) is a set of IEEE specifications that define various aspects of a wireless local area network. It consists of standards such as 802.11a and 802.11g (which define PHY and MAC layer of the WLAN), 802.11e (which defines QoS enhancements), and so on.

Access Point (AP): An AP is a layer 2 device that allows hosts in a wireless LAN to communicate with each other. It usually also provides the wireless devices with connectivity to the wired network.

Distributed Coordination Function (DCF): DCF is a MAC mechanism for providing channel access to 802.11 devices. Unlike PCF, it does not require a central coordinator.

Enhanced 911 (E911): A location technology mandated by FCC that would allow telephony service providers to locate callers in case of emergency calls. This is also required for emergency calls made using wireless IP telephony or IP telephony when it is harder to implement because of its mobile nature.

Handoff: In general, a handoff is passing an association from one entity to another. In the context of 802.11, a handoff is a transfer of association from one AP to another. A handoff is required when the current AP's signal quality becomes poor and another AP with a better signal quality is available.

IP Telephony: Use of the packet-based IP network for transporting voice calls instead of the traditional circuit-switched networks.

Jitter: In the context of IP telephony, jitter is the variation in the arrival rate of voice packets. A high jitter value leads to poor voice quality as perceived by a user.

Media Access Control (MAC): A mechanism for mediating access to each of the contending devices sharing a common resource for communication, such as a cable in case of Ethernet or the electromagnetic spectrum in case of 802.11.

Mobile IP: An IP extension for facilitating seamless operation of mobile applications. It allows hosts to roam—that is, change their point of attachment to the IP network while keeping the same IP address.

Mobility Management: In the context of wireless IP telephony, refers to mechanisms (at various layers of

the network stack) to enable seamless communication (for ongoing as well as new calls) for a user who is mobile.

Packet Latency: In the context of IP telephony, refers to the delay in transporting a voice packet from a sender to a receiver. A high packet latency leads to poor voice quality.

Point Coordination Function (PCF): A MAC technique for providing channel access to 802.11 devices that uses a coordinator (unlike DCF) that is usually located at an AP.

Public Switched Telephone Network (PSTN): The publicly available, circuit-switched traditional telephony network.

Quality of Service (QoS): Refers to a mechanism for providing performance guarantees in the transportation of packets over a network. In the context of IP telephony, it refers to providing guarantees for transportation of voice packets on the IP network, which has traditionally only provided a best effort service in terms of packet loss, jitter, and latency.

Vertical Handoff: A handoff between heterogeneous access technologies—for example, between WLAN and 3G (cellular).

Voice over Internet Protocol (VoIP): Transmission of voice over an IP network as packets.

Wireless Fidelity (WiFi): WLAN based on 802.11 standards.

Wireless IP Telephony: Use of IP telephony over a wireless IP network, such as that based on the 802.11 standards (WiFi).

INTRODUCTION

Wireless mobile Internet has been an important topic of research within academia and industry in the past few years due to the popularity and dominance of the Internet services in our daily lives and the corresponding desire to have such services ubiquitously, regardless of location and time. The wireless Internet therefore will have a much broader meaning than a simple extension of the Internet into the mobile environment. Wireless Internet is really about the integration of the conventional global Internet platform with other advanced telecommunications technologies, so that all communications services of human beings, including Internet protocol (IP) services, could be covered anytime, anywhere, and through the best available access technology. The wireless mobile Internet, which was a dream just few years ago, is now progressing so fast that it could revolutionize the whole framework of the telecommunication industry. Because of the extensive

progress achieved during the last decade in the design of wireless access technology, switching and routing in the Internet, and sophisticated hardware and software, such a comprehensive Internet technology is no longer a dream but a practical reality. Whereas the first cellular-based mobile Internet services provided users with flavors of an actual wireless mobile Internet system, more research is needed to achieve the systematic goals of this network (Jamalipour 2003). Figure 1 illustrates some assumptions of a mobile Internet system.

Mobile and wireless Internet, as the name specifies, should provide a seamless transition from geographically fixed domain to a mobile environment. In this case, *seamless transition*, means that there should be no sensible change for a user who is connected to the Internet while moving from a fixed domain to a mobile domain. In a broad sense, this could even be the case when a user moves from a wireless network domain to another

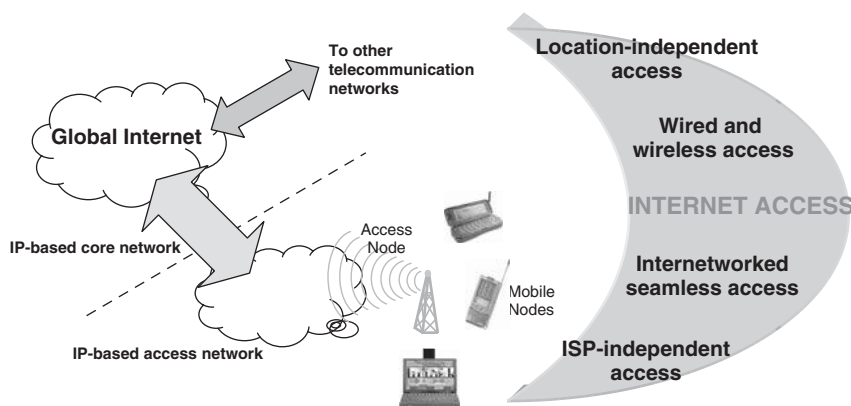

Figure 1: Internet access in a mobile environment

wireless network. The Internet access for the user should be independent of the access technology used for the Internet services.

The current network architectures used in either the wired Internet or the cellular networks would be neither appropriate nor efficient for future wireless mobile Internet, even if we assume that the cellular networks will provide the major infrastructure of the mobile Internet. Cellular networks simply cannot offer sufficient bandwidth and data rate for the mobile multimedia and Internet. The wired Internet, on the other hand, faces serious difficulties in providing service to mobile Internet users. Much of the literature in recent years has discussed this issue and how it is possible to change the network architecture to be utilized for mobile Internet (Umeshira et al. 1999; Macker, Park, and Corson 2001; Oliphant 1998; Norenberg II 2001; McCann and Hiller 2000; Ramjee et al. 2000; Mobile Wireless Internet Forum n.d.). One major issue is making the core network independent of the underlying access technology.

Currently there exist several access networks, such as second- and third-generation (2G and 3G) wireless cellular, wireless local area network (WLAN), and satellite, that offer a broad range of services. Access-specific end terminals are required for subscribers to enjoy seamless services across these networks. At present, there is no single system available that can effectively replace all of these technologies and offer all services using the same terminal. As a result, research is under way to develop the next-generation network (4G or beyond 3G [B3G]) that will facilitate seamless mobility across heterogeneous technologies by means of a single handheld terminal. This envisaged network will be a fabric of inter networked existing and future access technologies (both wired and wireless) integrated together through an IP version 6 (IPv6) transport protocol (Jamalipour, Mirchandani, and Kibria 2005; Mirchandani, Kibria, and Jamalipour 2005).

At the same time, extensive research is under way toward systems based on Institute of Electrical and Electronics Engineers (IEEE) standards for a wide coverage area from personal area networks (PANs) of the IEEE 802.15, local area networks (LANs) of the IEEE 802.11, metropolitan area networks (MANs) of the IEEE 802.16, and finally the wide area networks (WANs) of the IEEE

802.20, a serious competitor of the cellular wide area networks such as 3G systems. In addition, there are activities toward the generation of standards for handoff and roaming among those IEEE families under the IEEE 802.21 standard. Because of the closeness of WLAN to the traditional wired Internet, these new standards can open new doors to the implementation of wireless and mobile Internet in the future. Figure 2 summarizes the cellular and IEEE standards for different coverage areas.

Chapter Outline

This chapter introduces the concept and architectural requirements of the future wireless Internet from cellular and IEEE standards points of view. The vast infrastructure already deployed for cellular 2G and 3G systems, together with the current research and development on next-generation networks (NGNs) and 4G and the integrated architecture of cellular and WLAN systems, constitutes necessary knowledge for future wireless Internet. These areas are covered in this chapter.

In the following section the concepts and fundamental topics of the wireless Internet are discussed. This section includes discussions on changes in future Internet services, changes required for the dominant Internet protocol suite, evolutions in telecommunications technologies (for voice and data communications), potential mobile Internet applications that must be supported in future networks, the concept of the future telecommunications networks working in heterogeneous and cooperative ways, and a summary.

Then the next-generation networks and the heterogeneity involved are further investigated. Next-generation network motivations and features, the problems with the conventional Internet protocol suite (and possible solutions), and a summary are provided. The following section looks at the new trends in integration of wireless LAN standards with the cellular networks to provide faster data communications where possible. In this section, major interconnecting architecture proposed in the literature is discussed. Next we look at IEEE standards and how they can provide a major role in future broadband wireless Internet services. The main IEEE standards, including

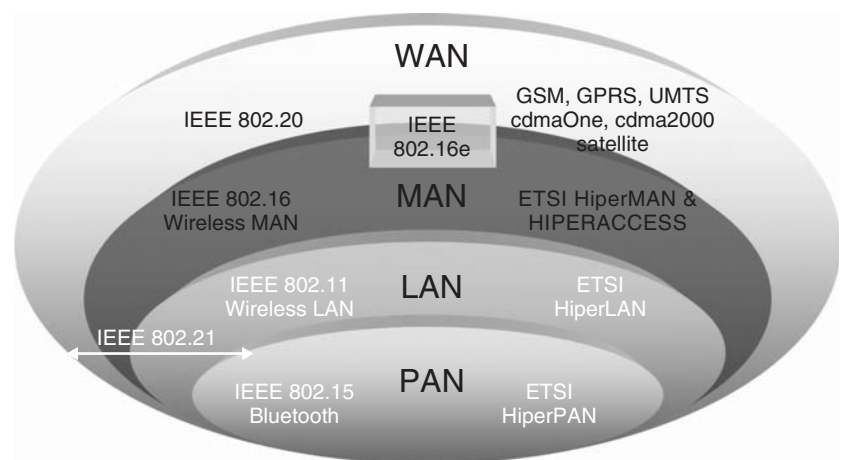

Figure 2: Coverage of IEEE standards and cellular systems

IEEE 802.11, 802.15, 802.16, 802.20, and 802.21, are reviewed and move the reader toward the realization of broadband wireless access and the Internet using these standards. The chapter closes with a conclusion.

CONCEPTS AND FUNDAMENTAL ISSUES IN WIRELESS INTERNET

The wireless mobile Internet will be different from its wired counterpart in the sense that the online service will be provided to a user regardless of the user's geographical location and the communications access network. The motives behind wireless Internet are the great success and popularity of the traditional wired Internet and the need to offer the service anytime and anywhere. This expansion of Internet service to a wide geographical area is not feasible unless several telecommunications technologies work cooperatively with one another. The mobility of a user among networks of the same types or different types, and ways to assure quality of service and handover management need to be solved before the complete wireless mobile Internet can be established.

In this section, we look at the changes that have taken place in the Internet world from a service point of view, and how these changes need to be handled by future networks. How the modular Internet protocol suite can establish the quality and security requirements of the mobile Internet of the future will be of primary importance.

Changes in Internet Service

The traditional Internet services were introduced based on the assumption of fixed networks with personal computers and servers connected through cables and located at fixed physical locations. Mobile Internet will change the types of service because the network devices and computers can be moved to different locations freely while maintaining their network connections. Services in the modern mobile Internet can transition from fixed domain to mobile domain, and vice versa. Services can also be transported from a mobile network (e.g., as a 3G system) to another mobile network (e.g., WLAN). An ideal mobile Internet will experience no noticeable change of service quality for a user moving from one domain (fixed or mobile) to another domain. This will be the main challenge of future mobile Internet design.

The access technology carrying the actual bits of data at the physical layer of the mobile Internet will have an important effect on maintaining service quality. At the same time, the mobile Internet should provide service independent of the access technology. No dramatic change in the quality of service (QoS) parameters—particularly those that can be sensed by users, such as data rate and delay—should be felt during roaming from one network to another network.

Because the current protocol stack model has a modular structure, such as one seen in TCP/IP, achieving the real multi-access technology mobile Internet would be difficult, if not impossible. Throughout this chapter we will introduce other methods to remedy such shortfalls. In the following subsection, we first summarize some changes

based on the assumption that the current protocol stack model is used.

Changes in Layer Protocols

During transition from the traditional wired Internet to the wireless Internet, network protocols and architecture change dramatically. In a mobile Internet system, the user should not feel a dramatic change in quality of service (QoS) for the application currently being used. The most noticeable quality measure is the connection speed or data bit rate, which is logically followed by the delay requirements. Changes in protocol affect all layers of the network protocol stack. At the physical layer (layer 1), mobile devices have to be equipped with multiple interfaces to different access networks, including wired examples such as Ethernet cable and dialup modem and wireless examples such as wireless LAN, infrared, and cellular modems. The physical layer has to include several interfaces to layer 2 in order to manage the best connection to higher layers, and if one connection cannot provide the required quality to the application, a combination of two access networks can be granted. Consequently, link layer (layer 2) has to be modified in order to simultaneously establish and maintain two or more connections via different access networks that are provided by the physical layer. This change in the link layer protocol can be incorporated, for example, in the design of the computer operating system (OS) functions. The multi-access inclusion in layers 1 and 2 is the start of a heterogeneous system configuration.

At the network layer (layer 3), Internet protocol needs major changes so that it can handle the routing and other usual tasks of the network layer in wired and wireless environments. Mobility of the IP address should be accommodated in the future mobile Internet. Signaling requirement of the IP layer protocol has to be simplified to provide more spectrum efficiency in future wireless access networks. IP addressing and global address translation among heterogeneous networks must be performed in protocol changes at layer 3.

The transport layer on top of the IP layer may be considered the main area of modification for future mobile Internet networks. The legacy design of this layer for wired networks avoids efficient use of the radio channel capacity; thus, major modifications and extensions are required at the transport layer with dominant transmission control protocol (TCP) and user datagram protocol (UDP).

In a mobile Internet, the mobile user does not see any difference between the currently available service providers at a given time and location, and it is assumed that a user may access the Internet regardless of his or her point of attachment to the network and the supporting access and core networks. Therefore, a system for authentication and authorization of users when moving across different networks must be established. Authentication provides the proof of identity of a user to the network that the user is going to access. This process is usually performed through an authentication function procedure. Authorization certifies what type of services may be provided to an authenticated user. Therefore, it is not sufficient

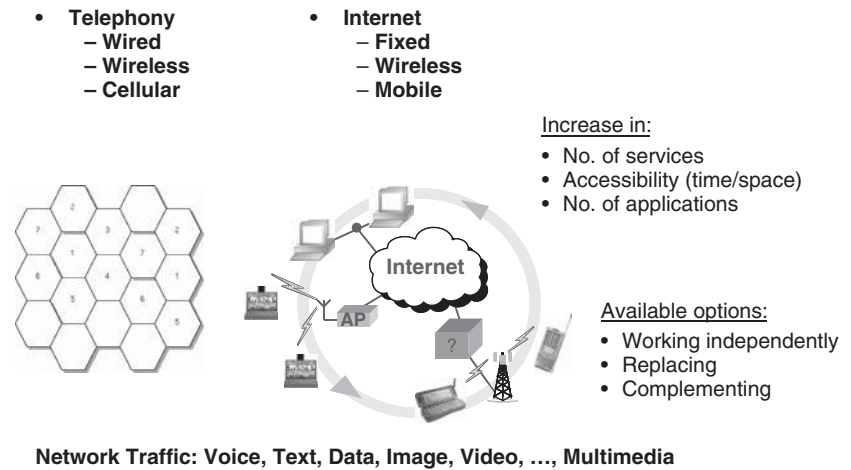

Figure 3: Evolution in telephony system and the Internet

that a user is in a capacity to connect to a network; the user has to be subscribed for a list of services that he or she will receive from the subscribed network. Accounting (the third A in the network AAA—authentication, authorization, and accounting) provides a database of what and when a user accessed while connected to a network. Accounting also provides the pricing and tariff calculation of different types of services received by the user from multiple network providers.

Mobile Internet will be shared among different telecommunication technologies and hence needs to share its limited resources. A sophisticated resource management is vitally necessary to share those resources among all coexisting technologies. Resource management schemes such as bandwidth management, admission control, congestion control, and so on will guarantee reliable performance of the network as well as a fair allocation of resources to all eligible users.

Evolution of the Telecommunications Technologies

The telephony system and the Internet have developed by very similar trends. Telephony has started with wired connections and switching and later evolved into wireless and cordless systems. As a result of the requirement to support more users, the cellular telephony concept (i.e., spatial and frequency reuse) and various multiple-access technologies were invented. Although at this time a large number of users are on mobile telephony networks, fixed telephony still plays a major role in telecommunications, both as an end-user service provider and as the backbone of the cellular telephony system. During the advancement of the telephony network, new services and applications were generated, and the accessibility of phone communications has greatly increased in time and space.

The global Internet infrastructure has also been initiated and greatly extended within the wired network. The Internet backbone includes a large number of high-capacity digital trucks, some supported by the public telephony system and even satellite channels, and wired switches and routers forming the global Internet infrastructure. The Internet services and applications have increased significantly, at a much quicker pace than their telephony

counterparts, and in a much wider range. Figure 3 summarizes the similarities between the two dominant telecommunications technologies.

The network traffic in both systems has evolved as well. The telephony system started with voice communications service and then found its way to data communications. The switches evolved to change the circuit-switched architecture into more data-friendly packet-switched networks. Soon, other multimedia traffic such as video was added to the list of traffic types. The Internet, on the other hand, began with lower rates for data communications and then increased its capacity toward high-speed data communications. Eventually it moved toward voice types of real-time traffic that require lower delay as used in voice over IP (VoIP) and videoconferencing over the Internet. Thus, it seems that there are many common points in the evolution of the two networks, which could offer different options for their cooperation in the future telecommunications infrastructure.

Fixed and Mobile Internet Applications

The next generation of the Internet should support a variety of services and applications, some via the conventional wired Internet, some via short-range mobility provided by the WLAN, some as a result of developments in cellular data communications such as short message service (SMS) and multimedia message service (MMS), and eventually others when wider mobility and Internet connectivity can be provided. Figure 4 shows some of these applications.

The mobile Internet applications are endless, and many new services are created everyday. The following list shows some examples of the applications that should be supported by the mobile Internet. Some of these applications require access to a different access technology (wired or wireless) depending on time and the users' location. Understanding these applications and services could be useful in the design process of future mobile Internet systems.

- **Vehicles**
 - Transmission of news, road conditions, weather, music via digital audio broadcasting (DAB)

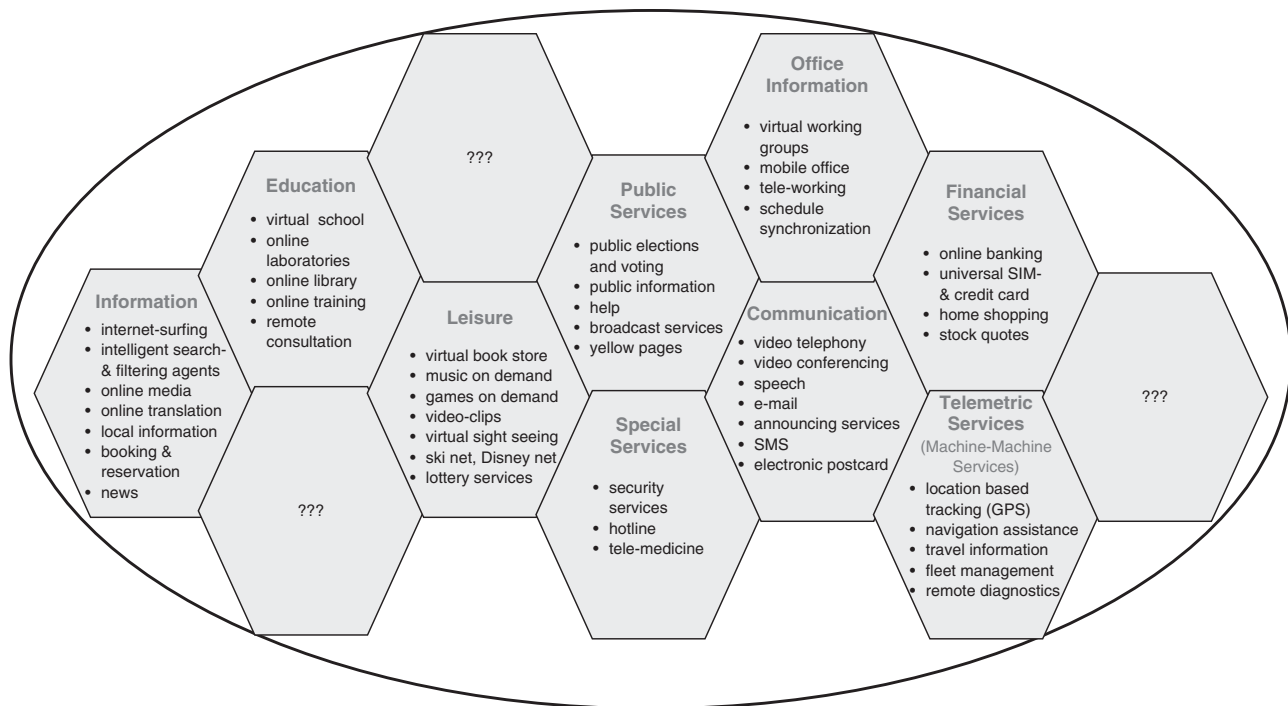

Figure 4: Fixed and mobile Internet applications

- Personal communication using cellular phones
- Position via global positioning system (GPS)
- Local ad hoc network with vehicles close by to prevent accidents, guidance system, redundancy
- Vehicle data (e.g., from buses, high-speed trains) can be transmitted in advance for maintenance
- Emergencies
 - Early transmission of patient data to the hospital, current status, first diagnosis
 - Replacement of a fixed infrastructure in case of earthquakes, hurricanes, fire, and so forth
 - Crisis, war, and so on
- Traveling salesmen
 - Direct access to customer files stored in a central location
 - Consistent databases for all agents
 - Mobile office
- Replacement of fixed networks
 - Remote sensors (e.g., weather, earth activities)
 - Flexibility for trade shows
 - LANs in historic buildings
- Entertainment, education, and so forth
 - Outdoor Internet access
 - Intelligent travel guide with up-to-date, location-dependent information
 - Ad hoc networks for multi-user games

Telecommunications Network of the Future

In order to support the future mobile and wireless Internet with all its services and applications, including those

traditionally supported by the telephony systems, it is vitally important to move toward a cooperative system that consists of all advanced telecommunications technologies held together by a reliable and efficient core network. This system will be the basic structure of the future mobile Internet. Figure 5 illustrates such a system, which will be discussed in more detail in this chapter.

The telecommunication system of the future will require horizontal and vertical communications among different access technologies such as cellular, cordless, WLAN, short-range connectivity network such as Bluetooth, satellites, and wired networks. Vertical communications refer to the communication interfaces between systems of different generations or with different coverage, whereas the horizontal communications applies to the systems and networks of the same generation or type. Such two-dimensional communications will provide an efficient use of advantages of each network to provide the ultimate service to users. Appropriate roaming and handover techniques among these networks for seamless mobility will be the key to the future mobile data networks and the Internet. Figure 6 represents a simplified model for such two-dimensional internetworking.

An advanced media access technology connects the core network to the heterogeneous systems. This core network will provide seamless and transparent service negotiations including mobility, security, and quality (such as data rate, delay, packet dropping probability, etc.).

Summary

Applications have been and will be the driving forces in the evolution of all telecommunications technologies, and this will be the case for the mobile Internet too.

Figure 5: Interoperated telecommunications architecture

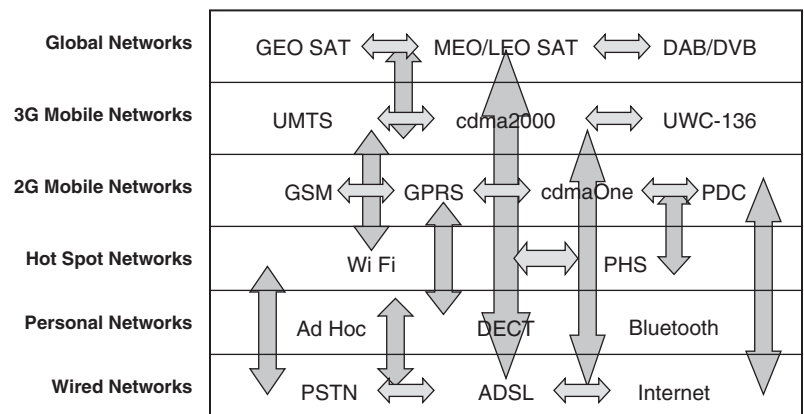

Figure 6: Two-dimensional internetworking

The success of the global Internet was mainly due to its accessibility and the usage of an open architecture, which has yielded to more affordable costs and higher popularity. Mobility will be the most recognizable feature of future telecommunications, and the wireless Internet has to find the best solutions to support mobility in heterogeneous access technology environments. Multimedia mobile applications will force future networks to be united under a common platform and to cooperate efficiently to complement the services of one another. The success of the mobile Internet will depend on the appropriate use of different technologies at proper times and in proper domains.

For the mobile Internet of the future, efficient heterogeneous traffic flow management and QoS management techniques are required. These techniques should be capable of delivering a variety of QoS and security on an end-to-end basis within the heterogeneous networks of wired and wireless segments. Traffic flow volume must be controlled by discriminatory preferences given to individual users and applications as a result of limited available spectrum. Yet, in order to keep the popularity of the Internet as it is now, best effort services should be continued for those users who want it. Best effort services are also necessary when providing the QoS is not possible

due to physical channel restrictions and/or network resource availability.

NEXT-GENERATION NETWORKS AND HETEROGENEITY

The emergence of several access technologies has resulted in a multitude of heterogeneous systems targeting different service types, data rates, and users. Whereas the migration from first- to second-generation cellular systems involved the transition from analog to digital technology, the evolution from second- to third-generation cellular systems is driven by the popularity of the Internet and the need for higher data transmission availability on the move. Different available access technologies—such as second-generation global system for mobile communications (GSM) and IS-95 (CDMAOne), the enhanced higher data rate third-generation packet-switched universal mobile telecommunications system (UMTS) and CDMA2000, the high-capacity/high-bandwidth WLANs (IEEE 802.11, HIPERLAN, HIPERLAN2), high-speed digital broadcast systems such as digital audio broadcast (DAB), digital video broadcast (DVB), and so forth—with their own distinct characteristics, complement one another (see Figure 6).

However, the absence of a single architecture to integrate all existing and future systems prevents the subscribers from enjoying reliable and global end-to-end connectivity through a single subscription.

NGN: Motivations and Features

The main motivation for the research in next-generation network architecture is based on factors such as:

- Demand for better availability of services and applications
- Global connectivity all types of services anytime, anywhere, and anyhow
- Rapid increase in the number of wireless subscribers who want to make use of the same handheld terminal while roaming
- Support for bandwidth-intensive applications such as real-time multimedia, online games and videoconferencing, and traditional voice service (VoIP)

The scalable and distributed next generation (or 4G) network architecture is expected to offer services in diverse setting such as indoor, outdoor, pedestrian, and vehicular. The services will be offered over a large range of overlapping access networks (e.g., WLAN, 2G, 3G, xDSL, DVB, DAB, etc.) that offer different data rates, coverage, bandwidth, delay and loss, QoS requirements, and so forth (Jamalipour, Mirchandani, and Kibria 2005; Mirchandani, Kibria, and Jamalipour 2005; Berezdivin et al. 2002; Frodigh et al. 2001; Gustafsson and Jonsson 2003; Kellerer and Vogel 2002). Figure 7 shows a general view of this type of next-generation system with overlapping heterogeneous access networks.

The key features visible to the user in such a network (per example in Figure 7) are:

- Mobile terminals will be able to auto-configure to the specific access technology at the location of the terminal.
- Subscribers will have access to the various services on offer and enjoy a wired LAN equivalent quality of

service, cost, and security, even while running real-time applications.

- Ubiquitous and seamless connectivity will be provided through effective mobility, resource, and QoS management schemes.
- The investments made by the subscriber will be respected by limiting the changes required in the multi-access mobile terminal in terms of hardware or software.

The key research objectives for such a harmonized heterogeneous 4G network architecture are:

- Integration of all existing and future communication access systems through a common IPv6 gluing mechanism.
- Development of a modular and scalable architecture with well-defined distributed network functionalities.
- Development of effective mobility, resource, and QoS management schemes to offer seamless connectivity and end-to-end QoS between peer end terminals.
- Development of physical architecture of a QoS-enabled mobile terminal capable of accessing the Internet and real-time services over a multitude of access technologies.
- Offering similar services (subject to network capacity and service policy) in both home and visited networks based on preferences and service agreements in the subscription.

IP Architecture Shortfalls and Improvements for NGN

It is widely agreed that IP will be the main component the next-generation mobile systems and therefore the future wireless Internet. With this assumption in mind, the traditional protocol stack used for IP shows some inadequacies for such an important role.

The Internet protocol stack is designed as a modular structure with a limited number of layers and their

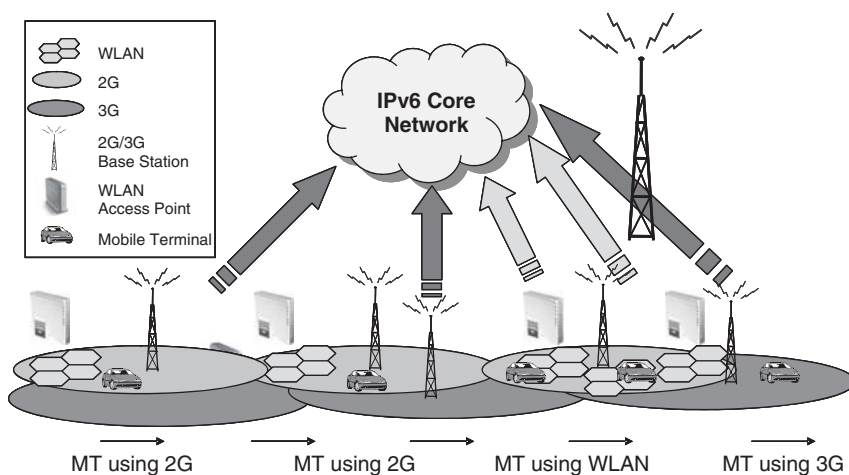

Figure 7: General view of the next-generation system showing overlapping heterogeneous access networks

associated protocols. Each layer uses services provided by its next lower layer and then provides new services to its next upper layer. In such a modular and layered architecture, communication is only possible between the adjacent layers. Figure 8 shows the conventional TCP/IP modular protocol stack. Numerous texts provide more information on the fundamentals of the TCP/IP protocol suite, including (Forouzan 2003; Stallings 2000; Comer 1999).

In the TCP/IP protocol stack, each layer is responsible for particular tasks. More specifically, the link layer (e.g., the Ethernet) provides connectivity to other network segments—that is, not to the hosts in different networks. The network layer (e.g., IP) delivers datagrams across multiple networks. Thus, a packet sent on one network can be transported to a host in a different network using IP routing mechanisms. The transport layer may be one of the two main protocols, TCP or UDP. TCP provides connection-oriented communications services, makes the communication reliable, and avoids network congestion, using its own flow and congestion control algorithms. UDP, on the other hand, provides a simple but unreliable transport mechanism for quicker communications required in some applications such as real-time and voice traffic.

Looking at this modular structure and defined tasks for layer protocols, the question is where to put the main elements necessary for NGN. In particular, for the QoS it becomes an important issue that the protocol stack can support voice, video, and other multimedia real-time services that require low delay performance. Also, the mobility among networks of the same technology (i.e., micro-mobility) and across networks of different technologies (i.e., macromobility) are unsolvable with the current structure.

In order to solve the problem to some degrees, extended structures for the TCP/IP protocol stack have been researched for many years. Figure 9 shows one example of the extended TCP/IP stack. In order to increase the IP address space and to ease the routing at the IP layer, new network protocols such as IPv6 have been introduced. Additionally, in order to improve the performance of TCP in the error-prone wireless channel, modified versions of the TCP have been widely introduced (Xin and Jamalipour 2005; Akyildiz et al. 2004). Additional sublayers for adaptive selection of networks and their associated media access control (MAC) protocols were also created. Note that in the extended protocol stack, the modularity of the protocol suite remains.

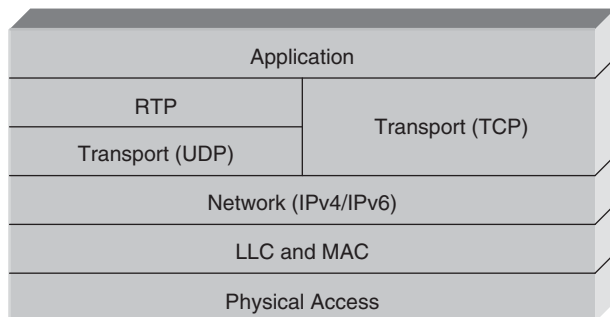

Figure 8: Conventional TCP/IP protocol stack

In Akyildiz et al. (2004), modifications of individual layer protocols are discussed that would allow the overall architecture to handle the heterogeneity in the NGN. In this paper, all changes have been made at the mobile host end, keeping the network side unchanged. In the proposed architecture called AdaptNet (Akyildiz et al. 2004), the link, transport, and application layers have been modified. At the application layer, in order to handle the fluctuations in bit rate and error rate of the wireless channel, adaptive source and channel coding techniques are employed. At the transport layer, an adaptive mobile-host-centric transport protocol is introduced—radial reception control protocol—which controls the connection congestion at the mobile host and changes the number of simultaneous transport interfaces when more bandwidth is required. At the link layer, an adaptive MAC protocol for seamless access control over heterogeneous networks is proposed. An adaptive error-correction scheme that changes the coding rate in accordance with the channel condition is also proposed.

Keeping the protocol suite in its conventional modular structure has produced many benefits in the past three decades, most notably the ability of independent people to design protocols for individual layers. However, as mentioned earlier, this modularity leaves QoS, security, and other requirements of the NGN out of scope or hard to achieve. Recently, an alternative protocol suite that includes cross-layer coordination among layers has been introduced (Carneiro, Ruela, and Ricardo 2004), as shown in Figure 10. The cross-layer architecture provides easier and quicker interactions among individual layers and changes the modularity structure of the conventional protocol suite. This, of course, may cause new problems in the independent design of protocols for layers, as more interfaces among layers than the usual interfaces to upper and lower layers must be considered.

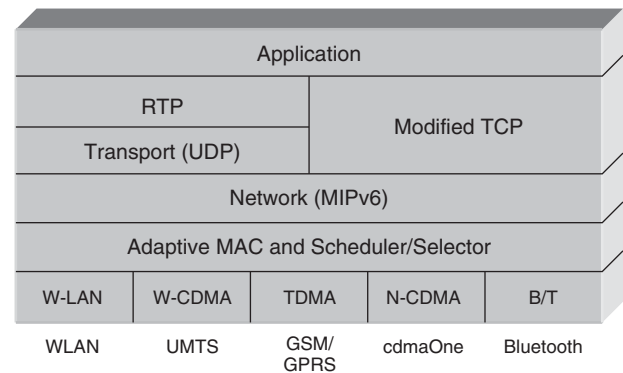

Figure 9: Extended TCP/IP protocol stack

Figure 10: Cross-layer architecture design for NGN

The cross-layer architecture design modifies the overall protocol stack, removes the modularity characteristic from it, and allows the interaction of protocol layers with layers other than adjacent ones.

Four separate vertical coordination planes are considered in the cross-layer architecture of Figure 10. These planes coordinate the information exchange and actions to be carried out by individual layers. The four planes are QoS, security, mobility, and wireless link adaptation.

In order to distribute QoS requirements (at the application level) and constraints (usually at the physical level) and the coordination of the efforts by layers to achieve an acceptable QoS level, the QoS plane is used. As an example of the need for such coordination, consider the change in error rate sensed at the physical and MAC layers. In the conventional modular structure, it takes a long time for the application to find any problem at the physical channel, as it has to be passed over several layers with their individual protocol processing delays. If the information for the physical layer bit rate or error rate can be passed directly to the application layer, the application can reduce the data-generation rate. This also reduces the network congestion (due to packet loss and retransmissions by the transport and link layer protocols) and provides a better QoS to the user application.

Coordination for the security also provides a much more efficient control compared with the traditional networks. The security plane in the cross-layer architecture coordinates the security arrangements usually performed at individual layers, which sometime require unnecessary redundancy and delay in supporting the service to the user.

The mobility plane in this architecture will solve the problem of the nonmobile structure of the conventional protocol suite. The information about the change in the access technology in a heterogeneous environment can easily and quickly be directed to the upper layers in vertical and horizontal handoff events.

The wireless link adaptation in the cross-layer architecture helps avoid harmful automatic repeat request (ARQ) reactions at the link layer and the transport layer, for example. When the channel encounters high bit error rate (e.g., wireless), link layer protocol tries to correct the error, which could take a long time before the TCP flow control mechanism acts. The wireless link adaptation plane can provide a direct way of transmitting this and similar information to the higher-layer protocols, so that such unnecessary actions are not taken by the individual layers.

New open and modular architecture specifically designed for NGN and the wireless Internet has been also proposed by the author, which can be further explored in Jamalipour, Mirchandani, and Kibria 2005; Mirchandani, Kibria, and Jamalipour 2005. The proposed architecture is open, hierarchical, layered, and modular, with cross-layer coordination and distributed network functionalities. Well-defined message interfaces enable the layers within the architecture to support the cross-layer coordination under dynamic network conditions. Novel augmentations in mobility and resource management schemes are proposed that result in the consolidation of the corresponding salient areas of B3G architectures discussed in the literature. Seamless services in the network can be accessed through

the reconfigurable multi-antenna end terminal. A common mechanism for control and signaling across heterogeneous networks is adopted to facilitate wireless system discovery and paging. The proposed architecture provides easier QoS and mobility management control in future heterogeneous systems. The proposed layered architecture for NGN is shown in Figure 11. The architecture includes advanced technologies such as software-defined radio (SDR) for different radio access networks (RANs). SDR would be an important element of the future NGN in which several access networks are available to the user and the best one should be used for particular applications.

Summary

The heterogeneity involved in the next-generation mobile networks and the wireless Internet requires modification of the TCP/IP protocol stack, which has been in place successfully for many years. This will be done either through an adaptive protocol design at individual layers with minimum layer interactions or through a cross-layer architecture redesign. Modification of the individual protocols to cope with the highly variable and unreliable wireless channel conditions could cure the problem for the short term. A good example of such activity is the numerous research efforts that have been carried out to improve the performance of the TCP over the wireless channel. Therefore, it is the authors opinion that for a longer-term solution the cross-layer architecture would be a better alternative because it can provide more effective solutions to the problems of QoS provisioning and security management in future wireless and mobile networks.

CELLULAR NETWORK INTEGRATION WITH WIRELESS LAN

Modern cellular networks are capable of providing high mobility, whereas a WLAN is known to have relatively high bandwidth. Ubiquitous data services and very high data rates across heterogeneous networks may be achieved by the use of a WLAN as a complementary technology to cellular data networks. Hence there is a strong need for efficient internetworking mechanisms between WLANs and cellular data networks. Such internetworking mechanisms are expected to be equipped with integrated authentication, integrated billing, roaming, terminal mobility, and service mobility (Salkintzis, Fors, and Pazhyannur 2002). A variety of internetworking architectures have been proposed by numerous researchers and groups. By and large, these proposed integration architectures may be categorized as tight coupling, loose coupling, and peer-to-peer networking (also referred as no-coupling; Wong et al. 2003; Varma et al. 2003). The definitions for these coupling mechanisms are as follows (Varma et al. 2003). (In the following, although reference is usually given to the IEEE 802.11 WLAN standard, similar discussions can be considered for other WLAN standards including the ETSI high performance local area network (HIPERLAN) and HIPERLAN2.)

In a tight coupling scenario, an IEEE 802.11 WLAN is connected to the 3G cellular core network (CN) via

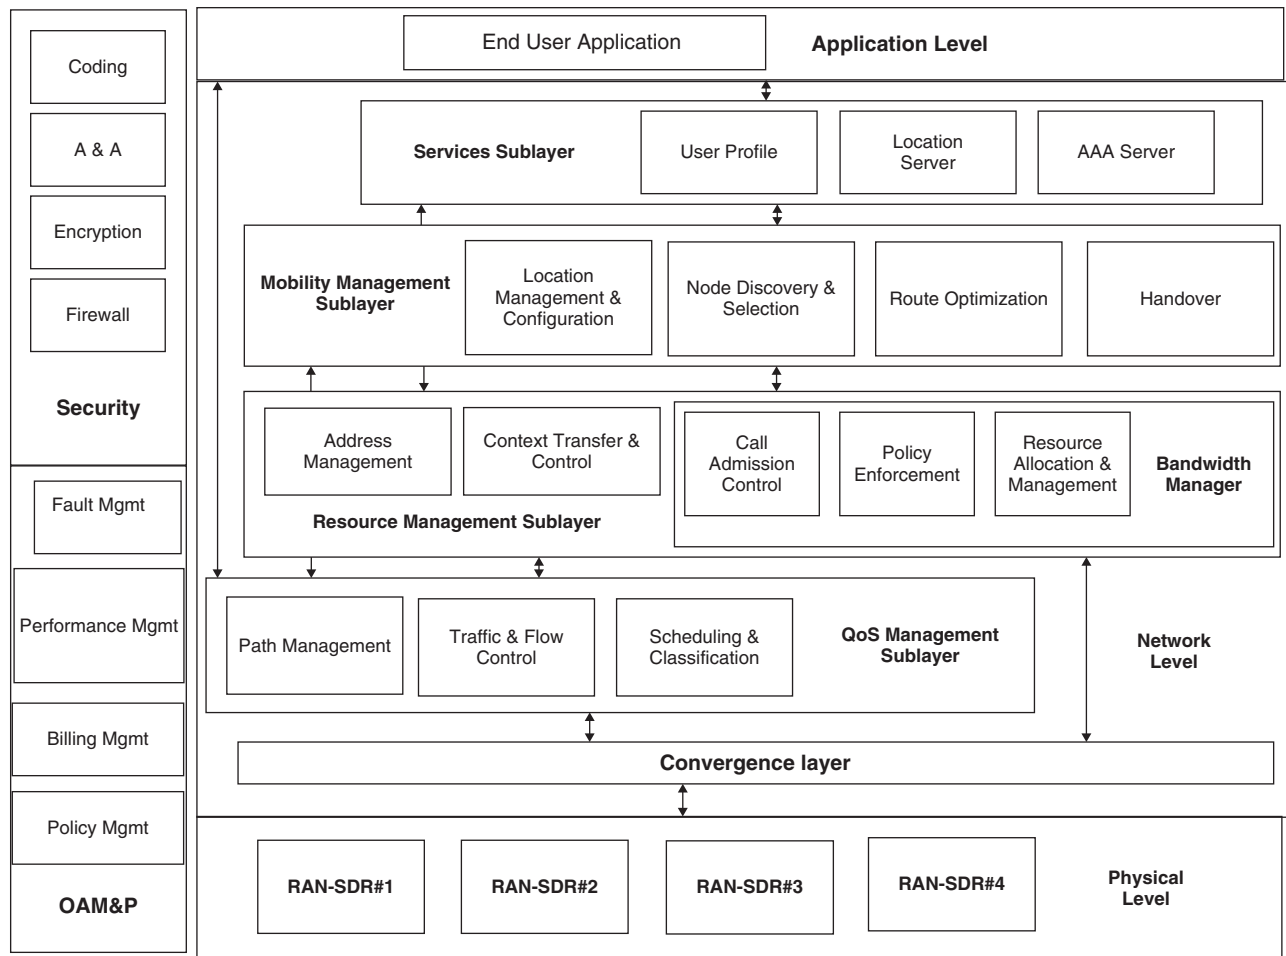

Figure 11: Layered and modular 4G network architecture

a serving general packet radio service (GPRS) support node (SGSN) emulator. Both data and UMTS signaling are transported by the IEEE 802.11 WLAN to the 3G CN via an SGSN emulator. Thus, the IEEE 802.11 basic service set (BSS) acts as another SGSN coverage area to the UMTS CN. On the other hand, a loosely coupled architecture transports UMTS signaling over IEEE 802.11 WLAN to the 3G CN, while data flows directly to the IP-based network. Figure 12 is a reference diagram that shows the tight and loose coupling points.

In tight and loose coupling methods, GPRS/UMTS signaling is carried over WLAN so that the two networks look like one from the network layer and above. In both of these cases, the 3G CN acts as the “master” network and the IEEE 802.11 WLAN behaves as the “slave” network. Although the last coupling mechanism, peer-to-peer networking, can be seen as an extension to the loose coupling architecture, it treats the two networks as peers (Wong et al. 2003). Mobile IP is used to provide a framework for mobility among these peers. The following sections provide a detailed discussion on various internetworking architectures, their advantages, and their disadvantages.

Tight Coupling Architecture

In tight coupling, the WLAN is directly connected to the 3G core network. Thus, the WLAN data traffic passes through

the GPRS core network before reaching the external packet data networks (PDNs). The key functional element in the system is the GPRS interworking function (GIF), which interconnects an IEEE 802.11 extended service set (ESS) to an SGSN via the standard Gb interface (Salkintzis, Fors, and Pazhyannur 2002). This is also referred to as an SGSN emulator (Varma et al. 2003). The GIF is the function that makes the SGSN consider the WLAN a typical GPRS routing area (RA) composed of only one cell. Therefore, the handover between WLAN and GPRS can be considered handover between two individual cells. It is also worth noting that the GIF and all interconnected WLAN terminals use a 48-bit IEEE 802 MAC address.

The WLAN adaptation function (WAF) is the main component that helps the mobile station (MS) to identify the MAC address of the GIF. Hence, there is a WAF implemented in every dual-mode MS as well as the GIF for 3G signaling and data exchange over IEEE 802.11 WLAN. WAF also provides the following functions: signaling the activation of WLAN interface as the MS enters a WLAN area, discovery of the MAC address of the GIF, helping the SGSN page a mobile station over the Gb interface, transferring LLC PDUs from the mobile station to the GIF and vice-versa, and supporting QoS by implementing transmission scheduling in the GIF and the MS. A typical architecture of the WLAN in its extended service

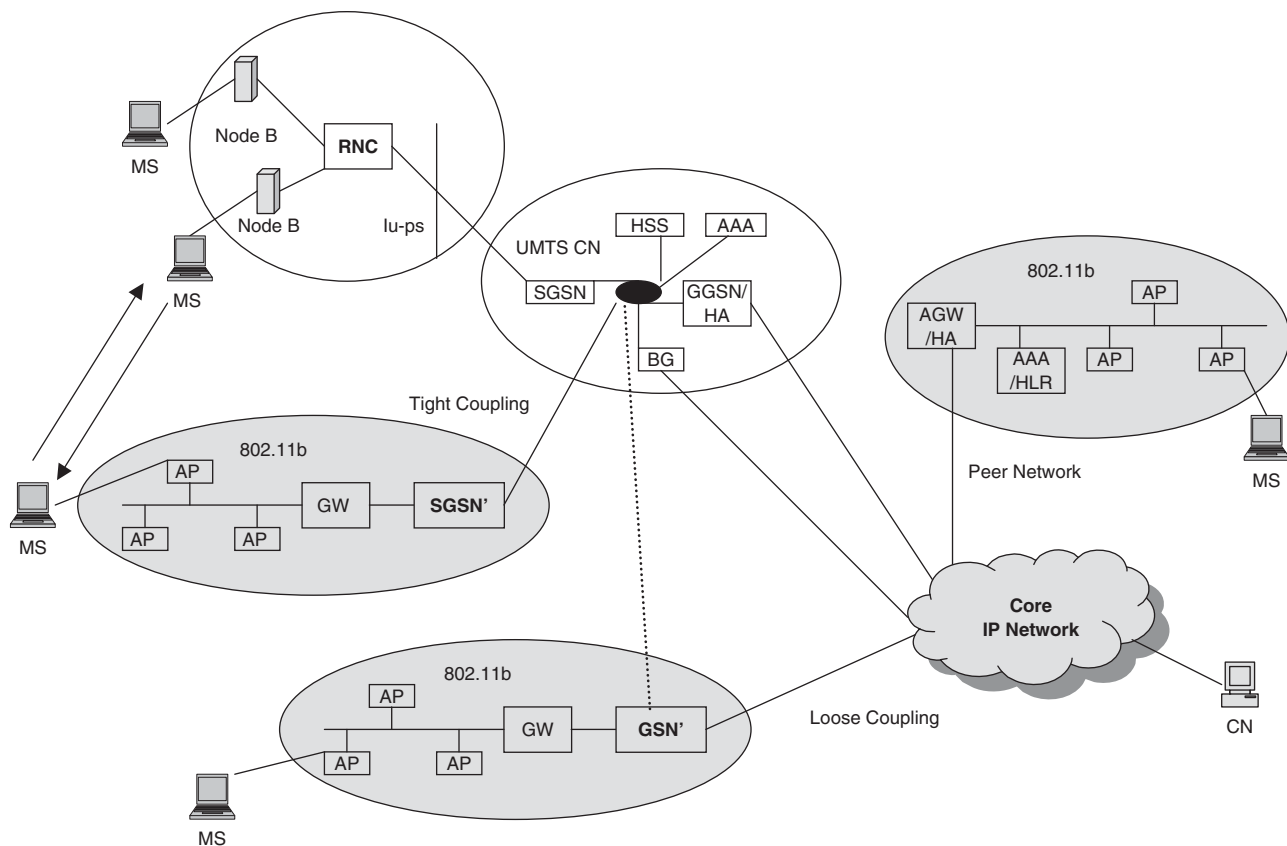

Figure 12: Alternative intergration architectures between WLAN and UMTS

set mode and its required components are shown in Figure 13.

Because the WLAN and GPRS networks connect to the same Gateway GPRS support node (GGSN), IP addresses will be assigned by the same pool. Hence, mobility across the two networks does not require a change of IP address to the MS (Varma et al. 2003). Lastly, the proposed tight coupling architecture is expected to have the following benefits (Salkintzis, Fors, and Pazhyannur 2002).

1. Seamless service continuation across WLAN and 3G networks
2. Less complicated mobility management because it follows GPRS/UMTS mobility management mechanisms.
3. Reuse of GPRS/UMTS AAA
4. Reuse of GPRS/UMTS infrastructure (e.g., core network resources, subscriber database, billing systems)
5. Increased security (GPRS/UMTS security can be applied on top of WLAN security)
6. Common provisioning and customer care
7. Access to core GPRS/UMTS services (SMS, location-based service, MMS, etc.)

Nevertheless, tight coupling can primarily be implemented in WLANs, which are owned by cellular operators. Thus, it lacks implementation capability in third-party WLANs. Furthermore there are cost and capacity

concerns associated with the connection of a WLAN to an SGSN.

Loose Coupling Architecture

Similar to the previous coupling method, loose coupling architecture is also a master/slave framework. The GPRS network acts as a master, and the IEEE 802.11 WLAN acts as a slave network (or a visiting network). In order to merely provide an IP connection through a WLAN, only the AAA traffic needs to be routed to the 3G CN and not the user data traffic (Salkintzis 2004a). In this scenario, only AAA signaling is exchanged between the WLAN and the 3G home PLMN (via the 3G visited PLMN) to provide authentication, authorization, and accounting (charging). Two alternative authentication models (or flavors) for loose coupling have been identified, which are described as the "IETF flavor" and the "UMTS flavor" (Findlay et al. 2002; ETSI 2001). The primary difference between the two is essentially the authentication server itself (ETSI 2001).

During the authorization phase, the 3G AAA server can establish policies for the user data traffic. It can also serve as a proxy to route AAA signaling to and from other 3G PLMNs. Thus the 3G AAA server is an important component introduced for the loosely coupled internetworking architectures. However, more advanced types of internetworking scenarios may also require the user data traffic to be routed to the UMTS CN (Salkintzis 2004a, 2004b).

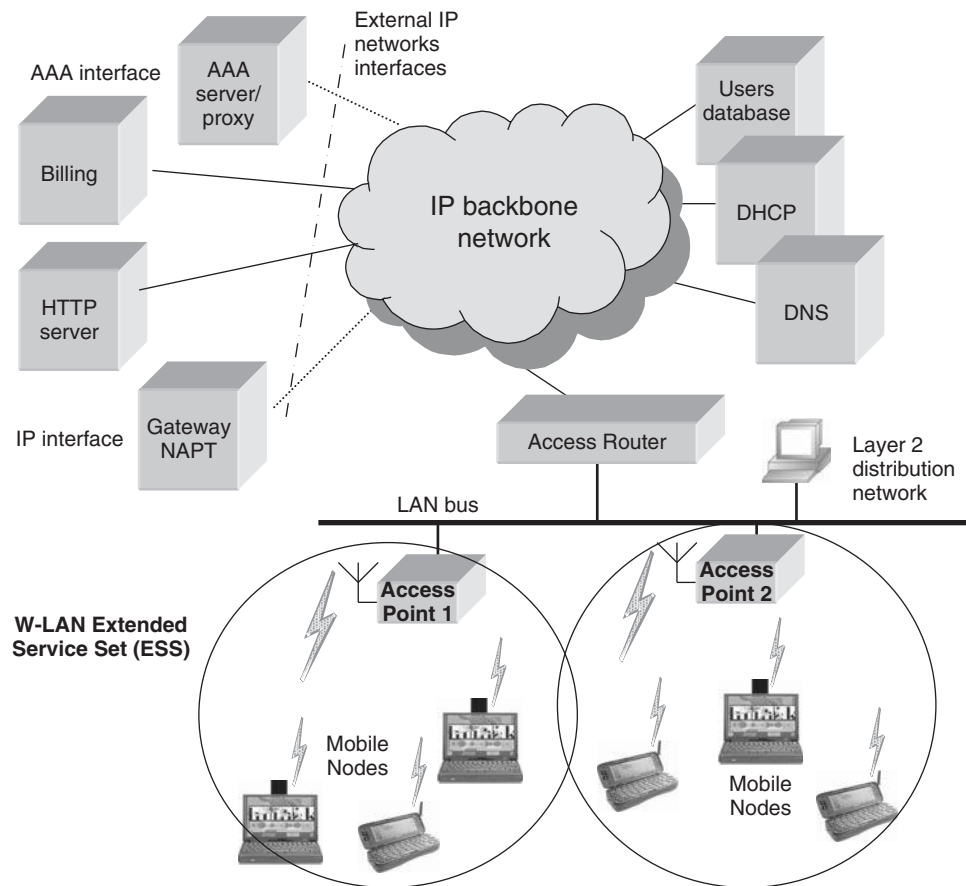

Figure 13: WLAN ESS architecture and its components in an integrated scenario

A clear advantage of the aforementioned method is that, because the data traffic is routed directly to and from the IP network (i.e., Internet) without having to route through the 3G network, a potential traffic bottleneck may be avoided. Since the 3G network and the WLAN are likely to be in different IP address domains, the MH will be allocated an IP address from the pool of addresses of the connected network. The changing of IP addresses may result in loss of connectivity. Therefore, for the loose coupling architecture, handoffs are less efficient and mobility can be considered only when the user is not in an active session (Varma et al. 2003).

Peer-to-Peer Networking Architecture

Unlike the previously discussed master/slave coupling methods, this approach treats the two networks as peers. In a peer-to-peer network architecture, 3G access and WLAN access may be provided by the same or different operators. Mobile IP (MIP) and AAA servers are used to provide a framework for mobility (Pahlavan et al. 2000). MIP is used to restructure connections when an MH roams from one peer network to another, and AAA servers provide AAA functionality.

The MIP framework consists of an MIP client (MH), a foreign agent (FA), and a home agent (HA). Outside of the home network the mobile host is identified by a care-of

address associated with its point of attachment. The MH registers its care-of address with its home agent (HA). The HA resides in the home network of the MH and is responsible for intercepting the datagrams addressed to the MH's home address and tunneling them to the associated care-of address.

When a 3G network and a WLAN are accessing a public IP network, MIP can be used in the following manner (Min-hua, Yu, and Hui-min 2003). The HA function may be implemented in the GGSN and the 3G network. As the MH (whose home network is, for example, 3G) moves to a foreign network (e.g., WLAN), it registers to HA (GGSN) its current care-of address through the FA at the foreign network. When the GGSN (HA) receives packets whose destination is the MH, it tunnels these IP packets to the FA and eventually reaches the MH. Likewise, the FA functionality may be implemented at the GGSN or SGSN of the 3G network.

Nevertheless, implementation of the HA does not necessarily have to be at the GGSN. The HA could also be implemented at an external IP network (Salkintzis, Fors, and Pazhyannur 2002). This architecture implements the FA functionality at the 3G and WLAN networks, which integrates with the HA located on an external IP network. However, both 3G and WLAN networks may need to subscribe to this IP network. Although peer-to-peer networking architecture is identified as a separate internetworking architecture, some literature merely considers it

a variation of the previously discussed loose coupling mechanism (Wong et al. 2003).

However, during the time frame between the MH leaving its current subnet to a new subnet, associating with a new FA, and updating the HA with the new care-of address, a packet loss (or disruption of service) can be noticed. This is because during this time interval the HA is still tunneling packets to the old FA's care-of address. Furthermore, as the distance between the MH and HA increases the service, the latency and packet loss increase. Thus, MIP framework may not be the best solution for frequently roaming users between two networks (Min-hua, Yu, and Hui-min 2003; Tsao and Lin 2002).

Summary

In this section, various architectures and levels for the 3G-WLAN internetworking were presented. The main mechanisms include tight coupling, loose coupling, and peer-to-peer coupling. Specific challenges encountered, advantages, and disadvantages of each of these architectures have been explored. Despite the fact that there is a vast range of proposed internetworking architectures, exist many open issues still exist issue is session mobility across WLAN and 3G cellular networks. For instance, when an MH with an active IP-based session (e.g., FTP or HTTP) moves from a WLAN to a 3G cellular network (or vice versa), the session must be seamlessly handed over from one network to another. Possible research questions that may arise from such a situation include how to detect the entering and leaving from a hotspot, which part of the network to handoff, and mechanisms to perform authenticated handoff. Thus, how to provide/enable seamless continuity of service across WLAN and 3G cellular networks can be ranked as a top issue.

Another important issue is to define a mechanism for user data routing via heterogeneous networks. How an optimal routing path can be decided is still an open issue (currently investigated by the 3rd-Generation Partnership Project [3GPP]). Nevertheless, matching the QoS requirements and service provisioning between WLAN and the 3G cellular networks can be considered a related issue. Provisioning of unified and integrated mechanisms for AAA and security in general is another high-priority concern. Amongst the related work done by the 3GPP in this area is to eventually adopt the IEEE 802.11i standard (per 3GPP's technical specification TS 33.234). Another related question is whether the AAA should be managed at WLAN, 3G CN, or independently. Furthermore, charging options such as postpaid, prepaid, and IP-flow-based charging must also be considered. Last but not least, terminal capabilities that support high data-rate applications, screen size, computational power, and network selection mechanisms must also be addressed.

IEEE STANDARDS TOWARD BROADBAND WIRELESS INTERNET

As previously mentioned (see Figure 2), IEEE has started a series of standards to provide a wide range of coverage for wireless and mobile data communications. Among

these, the most popular standards are the IEEE 802.11 WLAN. The WLAN has already become part of cellular networks, realization of the wireless Internet, through integration with UMTS and other 3G systems to provide broadband Internet access to indoor and high-population environment. This will definitely supplement the cellular 3G networks with much higher data rates than a cellular system can provide, particularly in areas such as buildings and shopping malls where it is primarily needed.

The success of the IEEE 802.11 was more or less a result of the fact that it could integrate itself in microprocessor chips and other computer hardware quickly due to its standardization and resolved compatibility issues. IEEE is going to follow the same approach for its new standards of 802.15, 802.16, and the proposed 802.20 and 802.21. In this section, we briefly review these standards and discuss their role in future broadband wireless Internet infrastructure.

IEEE 802.11 WLAN

One of the extensions to the wired Ethernet is the wireless LAN, defined in the IEEE 802.11 standards (Crow et al. 1997; IEEE 802.11 n.d.). Wireless LAN has become very popular for providing mobile Internet access to office and campus buildings due to the ease in movement of users connected to the Internet. IEEE 802.11 standards define a set of media access protocols to extend the wired Ethernet into the wireless domain. In 1985, the Federal Communications Commission (FCC) modified the radio spectrum regulations for unlicensed devices so that wireless LAN could operate within the industrial, scientific, and medical (ISM) bands if the equipment operates under 1 watt of power. The 902 MHz and 5.725 GHz bands can be used only in the United States, whereas the 2.4 GHz band is available globally (Forouzan 2003). The usage of unlicensed ISM frequency spectrums simplifies deployment of a new wireless LAN with very little, low-cost equipment. Nomadic Internet access, portable computing, multihopping, and ad hoc networking are some of the applications of wireless LAN technology. Depending on the standard, wireless LAN can achieve a speed of 2 (IEEE 802.11), 11 (IEEE 802.11b), or 54 (IEEE 802.11a/g) Mbps, in an ideal situation and with good wireless channel conditions.

In principle, a wireless LAN domain can be provided easily through an access point (AP) cabled to the usual wired Ethernet in a LAN system. Therefore, the access point can be seen as a router or a hub connecting several end hosts to the LAN system. The only difference is that the end host will access the AP through wireless radio channels, rather than cables. Because each AP gives access to several end machines, some type of multiple-access control has to be established by the AP to share the wireless channel among all end users. Spread-spectrum technologies (e.g., direct sequence and frequency hopping) are used for this purpose in the standard. In newer version of the standard, orthogonal frequency division multiple access (OFDMA) is used.

Each AP in a wireless LAN system can provide coverage to mobile Internet users in an area up to a maximum of 500 meters in radius. Therefore, with several APs it is possible to establish a cellular-like wireless LAN. In such

a case, cellular-type issues such as handoff and maximum capacity will become apparent. The users of a wireless LAN system can obtain an IP address through a dynamic host configuration protocol (DHCP), similar to a dialup connection, or by having a fixed IP address provided by their network administrator, similar to a desktop user (see Figure 13).

The technology provided by the IEEE 802.11 also allows users to dynamically form a private network without the need for an access point (Toh 2002). Therefore, it is possible to make a temporary network of computers (e.g., during a meeting) in which no single computer is the central server. All users will be on the same level of the network hierarchy. The computers in this network can exchange their data files through the wireless LAN network, which could be isolated from other local wired and wireless networks. This is a very basic implementation of a mobile ad hoc network, which clearly does not have any infrastructure behind it. The Internet Engineering Task Force (IETF) has a working group called the mobile ad hoc network (MANET) that develops the RFCs and standards for this emerging technology.

The IEEE 802.11 standard defines two types of services for the wireless LAN: the BSS and the ESS. In the basic service set, a network of computers is established either with a central base station (access point) that can connect the users of wireless LAN networks to the other parts of the wired network, or without a central base station, which provides an ad hoc network between several users without any access to other parts of the network.

Two or more wireless LANs that are using the basic service set can be connected through any of the IEEE LAN standards such as Ethernet (IEEE 802.3) to make an infrastructure of wireless LANs, so that the system covers a larger geographical area, similar to the concept of cellular networks. This configuration is the extended service set for the IEEE 802.11 standard. The wireless LAN illustration shown in Figure 13 is based on an extended service set configuration.

Two types of MAC are defined by IEEE 802.11: distributed coordination function (DCF) and point coordination function (PCF). DCF is the basic MAC protocol for wireless LAN and is the only access for ad hoc networking types of configuration. DCF is a contention access technique, which means that wireless LAN users need to compete to get a channel for data transmission. DCF is based on the fundamental Internet MAC protocol carrier sense multiple access (CSMA) with additional collision avoidance (CA), which makes it CSMA/CA (Forouzan 2003; Stallings 2000). One reason for using CSMA/CA in wireless LAN and not the usual CSMA with collision detection (CSMA/CD) used in wired LANs is that detecting a collision is not as easy for wireless media as it is for wired systems. In addition, in the case of wireless channels there is always the possibility of becoming involved with the *hidden-terminal problem*.

On the wired network, detection of another signal from a user can be performed by measuring the current signal power on the wire. However, in a wireless environment, it is possible that a user is in range of the base station and thus visible by it, but outside the range of another user, who is also seen by the base station. This phenomenon

is called the hidden-terminal problem. Therefore, when a user wants to transmit a packet over the radio channel, detecting the radio signal power would show only other users in his range and not the hidden terminals. If the user transmits a packet at the same time another hidden-terminal transmits his packet, both packets will be lost. The hidden-terminal problem is illustrated in Figure 14.

To avoid the hidden-terminal effect the wireless MAC needs to add extra packet exchange before a transmission to make sure that no one else transmits at the same time. Therefore, the base station in the wireless LAN acts as a server that allows a user to transmit (or not) after a request proposal. This can be done through the use of two short control frames called request to send (RTS) and clear to send (CTS). An RTS frame is sent by a sender and includes the duration of the data packet and the acknowledgement packet. The intended receiver can reply with a CTS frame, which gives an explicit permission to send to the sender. Because all other terminals in the wireless LAN network can listen to this frame exchange, they will know about the future data transmission and can avoid interfering with the transmission. The RTS and CTS frames are short; therefore, there is less probability of being involved in a collision with other packets. In addition following successful exchange of these frames, subsequent (long) data transmission between the two terminals should be collision free.

The point coordination function is implemented on top of DCF for time-sensitive transmissions in an infrastructure wireless LAN architecture. PCF uses centralized, contention-less polling access by utilizing a software package called point coordinator (PC) (IEEE 802.11 n.d.). PC software is located at the base station and polls users, one after another, to avoid any contention for their transmissions. As the PCF runs over the DCF, the sensing process of DCF, is performed at the beginning of the PCF polling cycle only once.

The IEEE 802.11 defines three types of specifications for the physical layer, based on frequency-hopping spread spectrum (FH-SS), direct-sequence spread spectrum (DS-SS) and infrared communications. Binary phase shift keying (BPSK) and quadrature phase shift keying (QPSK) were used as the modulation schemes in DS-SS

Figure 14: The hidden-terminal problem

specifications of wireless LAN for its early standard, for a bit rate of 1 and 2 Mbps, respectively. Other modulation schemes were added later in IEEE 802.11b and IEEE 802.11a standards to allow higher bit rates of 5.5 and 11 Mbps in IEEE 802.11b and 54 Mbps in IEEE 802.11a. In IEEE 802.11b, the MAC and logical link control (LLC) layer protocols are kept the same as in the original IEEE 802.11 and only the physical layer has been modified. For IEEE 802.11b, DS-SS is utilized. Dynamic rate shifting is also allowed in IEEE 802.11b so that in a noisy environment bit rate can be decreased from its highest 11 Mbps dynamically to 5.5, 2, or 1 Mbps.

IEEE has recently added new members to the 802.11 family in order to provide QoS, security, and higher speed. The IEEE 802.11e adds new QoS features to the originally non-QoS WLAN and supports multimedia and other applications that require delay limits such as VoIP, video on demand, and audio on demand. These are essential for the WLAN to reach markets in the emerging area of home networking. The IEEE 802.11i adds security features to the weak security protocol embedded in the original 802.11 called wired equivalent privacy (WEP). The new advanced encryption standard (ESA) provides greater levels of security compared to the WEP and even to the Wi-Fi protected access (WPA) security standard. Security was a weak point in the IEEE 802.11 standard because as it was originally designed for working in a closed area with simple architecture. After it gained popularity in small business and open areas, WLAN had to save itself from malicious attacks. In response to this need, the new IEEE 802.11i has been developed, which includes major security upgrades compared to the original standard. In addition, IEEE 802.11n provides much higher data-rate speed at levels of 100 Mbps and above. There are many new working groups in IEEE 802.11 created for specific purposes and tasks. IEEE 802.11r, for example, specifies fast BSS transitions that will permit connectivity for fast handoffs from one base station to another (e.g., for vehicular application) in a seamless manner. With regard to real-time applications such as voice, the normal 802.11 handoff procedure requires excessive delays, which makes it impractical for such uses. Therefore, a main application for IEEE 802.11r will be voice over wireless LAN networks. IEEE 802.11k is another proposed standard for how a wireless LAN should perform channel selection, roaming, and transmitting power control to optimize network performance. The IEEE 802.11k aims to redefine and improve the way traffic is distributed and managed within the network. These protocols will not be further discussed here because they are outside the scope of this chapter.

IEEE 802.15 WPAN

Whereas the IEEE 802.11 was designed to provide high-speed data transmission to local area network users, the IEEE 802.15 (n.d.) targeted short-range connectivity at very high speeds of hundreds of Kbps. Such connections can be used to connect peripheral devices to computers, headsets to mobile phones, mobile phones to computers, and so on.

The IEEE 802.15.1 was adopted from Bluetooth specifications, originally designed for use with PAN. This

version is fully compatible with Bluetooth version 1.1. Two technical groups (TGs) work on different data rates; TG4 works on low data rates to provide data speeds of 20 Kbps or 250 Kbps, and TG3 works on high data rates to support data speeds of 11 Mbps to 55 Mbps.

Using this standard, up to 254 network devices can be supported with dynamic device addressing. It also supports devices in which the latency is critical, and it consists of full handshaking, security provisioning, and power management. There are sixteen channels in the 2.4 GHz band (similar to the IEEE 802.11b/g), ten channels in the 915 MHz band, and one channel in the 868 MHz band.

There are also plans to redefine the IEEE 802.15 specifications to work with the specification and description language (SDL), particularly SDL-88, SDL-92, and SDL-2000 updates of the International Telecommunications Union (ITU) recommendation Z.100.

The IEEE 802.15 will provide the lower connectivity level to the IEEE 802.11 WLAN standard and therefore complete the path between the personal and area networks.

IEEE 802.16 WMAN

The IEEE standard 802.16 was originally published in December 2001, for fixed point-to-multipoint broadband wireless systems operating in the 10–66 GHz licensed spectrum (IEEE 802.16 n.d.). Because this band requires line of sight (LOS) between the transmitter and the receiver, an amendment called IEEE 802.16a was approved in January 2003 to provide non-LOS communications in the 2–11 GHz spectrum, delivering up to 70 Mbps at distances up to 30 miles.

The main purpose of the standard was bridging the critical connection that links homes and businesses with their Internet service providers. Data slowdown in the last mile of networking path can impact the entire Web browsing experience and limit the performance of the promising services such as video on demand (VOD) and multimedia-filled Web connections. In that sense, the IEEE 802.16, which subsequently took the name Worldwide Interoperability for Microwave Access (WiMAX) set its vision on blanketing sections of cities and rural areas that are not wired for broadband, or providing an alternative to wired connections in places that are connected. Therefore, with such a vision, WiMax will compete directly with local phone and cable companies that offer wired Internet access such as asynchronous digital subscriber line (ADSL), cable modems, and leased lines.

Using the original concept of the IEEE 802.16, in which point-to-multipoint data communications were considered, a service provider sets the transceiver antenna on top of a tall building. The signal reaches the clients on a LOS basis or, in some cases, through multipath bounces from other buildings. The received signal is decoded and unencrypted, and the payload is extracted. Inside the client's building the WiMax signal can be shared via other standards such as the IEEE 802.11 WLAN access points.

WiMax was not the first attempt at broadband wireless access (BWA) on a MAN range. Much work was done and some testbeds were implemented in different locations with good results. The major change in the WiMax design

was to make it standard so that it can utilize inexpensive hardware, as happened with the WLAN WiFi standard. To achieve this goal, a WiMax Forum has been established to create the standardizations and fix the compatibility issues among products, similar to the development stream previously followed for WiFi by the WiFi Alliances. The Forum began in January 2003 and currently includes major partners working on BWA products.

The later version of IEEE 802.16a for non-LOS applications, started in January 2003, operates in licensed and unlicensed bands of 2.4 and 5 GHz using OFDM similar to the IEEE 802.11a and IEEE 802.11g WLAN standards. Another standard 802.16b is also under development by IEEE for use in the licensed spectrum 11–66 GHz band. More recently, IEEE 802.16d has begun to take the place of its 802.16a counterpart with regard to better performance.

In the IEEE 802.16, different from the WLAN family, every base station dynamically distributes information about the uplink and downlink bandwidth to subscribers' stations using time division multiple access (TDMA). The MAC protocol does not use the carrier sense multiple access (CSMA) used in WLAN. Instead every station needs to get the permission and allocated bandwidth for data transmission. Therefore, since no packet contention is involved (as it is in the 802.11), the IEEE 802.16 can provide QoS to the clients. With the new efforts to bring the WiMax inside the processor chips in laptop computers, it is expected that the WiMax will be available soon for personal users. Although WiMAX's role as a MAN provider can be misunderstood by its LAN counterparts, specific differences in design of the IEEE 802.11 and 802.16 allow these two to work with each other rather than compete. In summary, the IEEE 802.16 is particularly designed for outdoor environments and optimized for those channel conditions in contrast to the IEEE 802.11, which is mainly designed for indoor channel conditions. 802.16e is the latest standard version in which mobility is being considered. 802.16e will add mobility to the 2 to 6 GHz licensed bands.

IEEE 802.20 WWAN and IEEE 802.21

The IEEE 802.20 (n.d.) is the proposal of the IEEE for mobile broadband wireless access networks (WAN) in wide geographical areas, something that is currently supported by cellular networks only. In this standard, a packet-based air interface is developed that is optimized for the transport of the IP-based services for mobile broadband wireless access (BWA). Potentially, the system will work in the licensed spectrum below 3.5 GHz. The IEEE 802.20 targets data rates over 1 Mbps per user at vehicular speeds up to 250 km/h. The application and targets of the IEEE 802.20 will be different from those considered by the IEEE 802.16e.

In order to roam from one IEEE standard to another (e.g., from a smaller area to a larger one, or vice versa), IEEE has proposed the new standard IEEE 802.21 (n.d.). In this Working Group, standards will be developed to enable handover and interoperability issues between heterogeneous networks, including both 802 and non-802 networks.

The IEEE 802.20, if completed, will provide a broadband high-speed mobile data network that will surpass the current deficiencies of cellular 3G networks and provide real broadband access to mobile users.

Summary

This section introduced some of the members of the IEEE standard family for providing broadband wireless Internet services at different ranges. Because all of these standards belong to the same family and are created from the same organization, they should be able to work easily and freely with one another. The complete set should provide a good environment for data communications in a wide geographical coverage area and at compatible data rates. The future of the wireless and mobile Internet will depend on how these new activities compete or complement the services of the previous cellular networks.

CONCLUSION

The development trend of the wireless Internet and next-generation mobile networks has now taken two distinct paths. One follows the path of cellular mobile systems and their long-standing and vastly deployed infrastructure all over the world. The evolution of the mobile cellular systems from the second-generation systems to third generation could revolutionize the amount and variety of data that can be transmitted over cellular phones. However, it won't be fast enough to equal the increase in speed of other Internet connections, mainly wired and wireless LAN systems. To supplement and help the cellular systems achieve better performance for bandwidth-demanding mobile applications, WLAN has become a partner in the integrated WLAN/cellular networks.

The second direction in broadband wireless Internet is the development of a series of IEEE standards for personal, local, metropolitan, and wide area networks, falling under the IEEE 802.1x and IEEE 802.2x standards. With the huge success and popularity of the IEEE 802.11 WLAN standard, the focus is now on other means of broadband wireless access standards, under the IEEE standard, which can provide an IP-friendly high-speed wireless network.

No matter how these rather exclusive directions develop during the next few years, the future of the mobile data and wireless Internet will depend on a heterogeneous solution that includes both approaches. From a security point of view, new security techniques should be developed that aim at higher layers of the network protocol suite in order to align with the heterogeneous nature of the physical access network. Bandwidth and resource management of large numbers of network users will eventually push the WLAN and WMAN standards to licensed spectrum, which could complicate the way these networks are used for daily wireless Internet services.

GLOSSARY

2G: Second-generation wireless mobile cellular systems, mainly consisting of global system for mobile communications (GSM) and CDMAOne.

3G: Third-generation wireless mobile cellular systems, mainly consisting of universal mobile telecommunications system (UMTS) and CDMA2000.

AAA (Authentication, Authorization, and Accounting):

The mechanism or architecture used in cellular network to authenticate users, authorize their services, and bill charges.

AP: Access point; the base station of a wireless LAN or other types of networks.

B3G: The temporary system name for those under development beyond 3G wireless mobile cellular systems; sometimes referred to as 4G and also known as next-generation networks.

BSS: Basic service set; the usual form of a wireless LAN network with just one access point and several mobile devices.

Coupling: The mechanisms or architectures to integrate the wireless LAN with the cellular networks using tight or loose coupling methods.

CSMA/CA: Carrier sense multiple access with collision avoidance; the media access control protocol used in wireless LAN to avoid too many packet collisions.

DAB: Digital audio broadcasting; a technique to digitally transmit high-quality audio signals such as radio, usually by satellite.

DVB: Digital video broadcasting; a technique to digitally transmit high-quality video signals such as television, usually by satellite.

ESS: Extended service set; the cellular topology network of a wireless LAN with more than one access point.

Handover: Change of service from one base station to another one for a mobile user during movement; sometime referred to as handoff.

Heterogeneous Networks: Networks that consist of different types of systems (e.g., cellular, wireless LAN, etc).

IEEE 802.11: The main wireless LAN standard developed by IEEE; has several versions including the popular 802.11b usually referred to as WiFi.

IP: Internet protocol; the main protocol used in the Internet at the network layer (layer 3), currently is in its version 4 (IPv4) but moving toward implementation of IPv6.

MAC: Media access control; the protocol at layer 2 of the network to control and govern the network access by multiple users.

MANET: Mobile ad hoc networks; networks that are prepared and maintained temporarily for a particular purpose such as establishment of a network among computers of people attending a meeting, or among mobile terminals in a battlefield.

Mobility Management: A set of techniques that controls the movement of a mobile device within a network and is usually composed of two elements: location management and handoff management techniques.

QoS: Quality of service; maintaining the required service condition to a user in a network, such as providing a maximum delay or minimum data rate speed.

Resource Management: A set of management techniques in a network to ensure that available resources, as required by the end terminal application, can be offered between peer end terminals, and to make sure

that resource allocation takes into consideration the current network conditions.

RSVP: Resource reservation protocol; a reservation control mechanism to provide quality of service to users by reserving resources beforehand; usually used in the Internet QoS establishment.

TCP: Transmission control protocol; the vastly used transport protocol in the Internet that provides a reliable data transfer among Internet terminals.

UDP: User datagram protocol; the unreliable transport protocol for the Internet that provides lower delay compared to TCP, as well as lower reliability, and is used for short message transfers or delay-sensitive applications.

VoIP: Voice over IP; a technique to deliver delay-sensitive voice packets over the Internet, which can provide lower costs to users.

WLAN: Wireless local area network; an extension of the traditional LAN systems in which the physical layer is changed from a cable or twisted pair into GHz radio frequency for easier scalability and mobility within a building or campus.

Wireless MAN: Wireless metropolitan area network; used to provide high-speed data access on a large scale outdoors. The main technology for this is the IEEE 802.16, also known as WiMax.

INTRODUCTION

Over the last few decades, the explosive growth of networks has had a drastic impact on the way people interact, live, work, conduct businesses, study, etc. In the past, although networking technologies such as radio and satellite have been used, most networks deployed have been predominantly wired. In recent years, we have experienced an explosive growth in wireless communication technologies. As a result, many different types of wireless networks have emerged on the market, each of which has been designed with specific purposes in mind. Wireless networks do not need wired connectivity and provide convenience to users particularly for those who are mobile. The wired Internet infrastructure is continuously being extended to connect to various types of wireless networking technologies (especially for the last mile access) that will provide wireless access to the Internet to mobile users. One of the important issues that has arisen with the rapid proliferation of a whole range of communication technologies is *heterogeneity*. To provide seamless connectivity across heterogeneous network systems remains a significant challenge. Heterogeneous networks can either refer to different types of wired, wireless, or wired-wireless (i.e., wired networks connected to wireless networks) networks. In this work, we focus on *heterogeneous wireless systems* and internetworking designs and strategies that can be deployed to enable users to exploit each wireless

networking technology best suited for the purpose the wireless network was originally designed (for example, factors such as coverage area, bandwidth). An additional challenge associated with the deployment of various wireless communication systems is the ability to seamlessly roam across different types of wireless access technologies. Doing so will minimize disruption to ongoing services while a wireless user is on the move. Integration and internetworking the various wireless networks are being achieved through the Internet Protocol (IP) technology. IP is compatible with, and independent of, any actual radio access technology. By exploiting IP as the core networking protocol, various wireless access technologies can be integrated together with high flexibility (see Figure 1). IP acts as an adhesive for providing global connectivity and mobility among heterogeneous access technologies.

Currently, no single wireless network technology is capable of simultaneously providing a low latency, high bandwidth, and wide area data service to a large number of mobile users. *Wireless Overlay Networks* (Stemm and Katz, 1998), a hierarchical structure of room-size, building-size, and wide area data networks solve the problem of providing network connectivity to a large number of mobile users in an efficient and scalable way. In an overlay network, lower levels are comprised of high bandwidth wireless cells that provide a small coverage area. Higher levels in the hierarchy provide a lower bandwidth but a much wider

access network. A mobile device with multiple wireless network interfaces can access these networks as it moves between different network environments. Next generation wireless systems typically constitute different types of access technologies. The heterogeneity that will characterize future wireless systems instigates the development of intelligent and efficient handoff management mechanisms that can provide seamless roaming capability to end-users moving between several different access networks.

Table 1 show some of wireless technologies which will be part of future heterogeneous wireless systems, along with their characteristics.

Some key features of next generation heterogeneous access networks include (Suk, Kai, and Hau 2003):

- High usability with anytime, anywhere connectivity.
- Support for multimedia services with low transmission cost.
- Integrated access networks with a common IP-based core.
- Use of multimodal devices, capable of supporting various types of network access technologies.
- Support for telecommunication, data, and multimedia services.
- Support for personalized services.
- Support for integrated service access from various service providers.

Overview of Wireless LANs

Wireless Local Area Networks (WLANs) are designed to support mobile computing in small areas such as buildings, parks, airports, or office complexes. The main attraction of WLANs is their flexibility. They can extend access to local area networks, such as corporate intranets, as well as support broadband access to the Internet, particularly at “hot spots,” public venues where people tend to gather (Varshney 2003).

WLAN Standards

The two most popular WLAN standards are:

- The European Telecommunications Standardization Institute (ETSI) has a standardized WLAN called HiperLAN2.
- The IEEE has created standards called 802.11b [IEEE 802.11b, 1999], 802.11a and recently 802.11g. The current 802.11b standard, commonly known as Wi-Fi, supports an 11Mbps/sec maximum rate as long as the users are located within a relatively short range (typically 30–50 meters indoors and 100–500 meters outdoors) of a WLAN base station. The deployment of 802.11a and 802.11g standards which allow bit rates of up to 54 Mbps/sec will pave the way for new types of mobile applications. The 802.11b and 802.11g operate in the 2.4GHz band, together with many other devices,

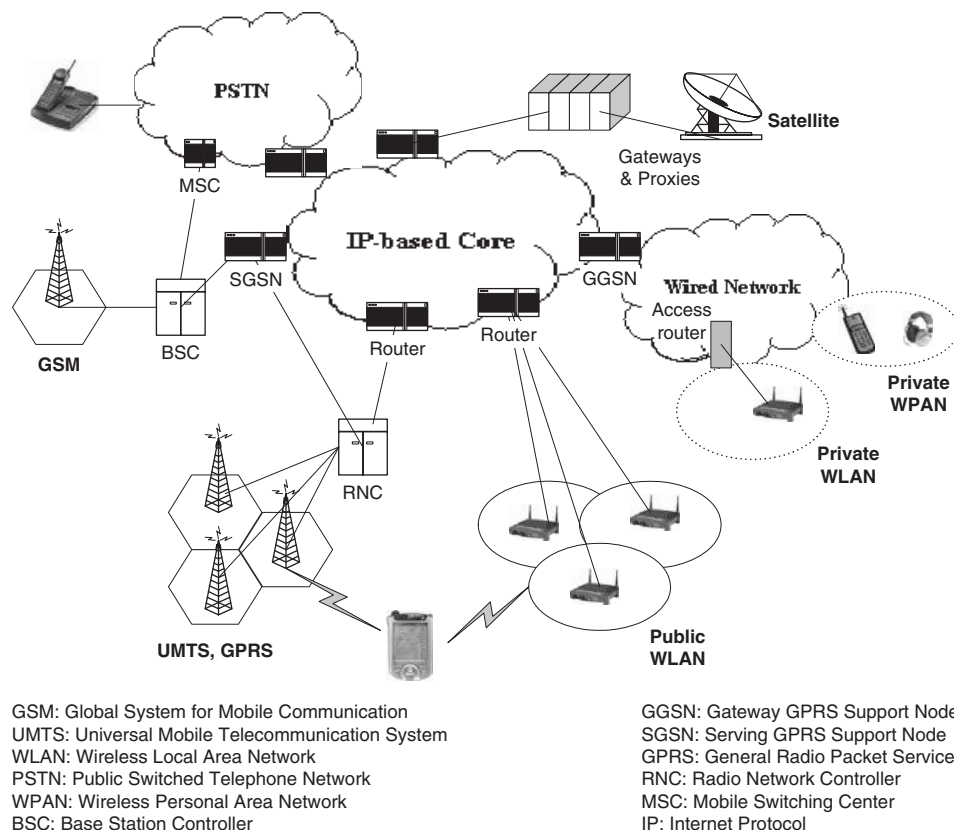

Figure 1: Future heterogeneous wireless access systems

Table 1: Characteristics of Heterogeneous Wireless Access Systems

	Access Network Type	Frequency	Data Rate	Coverage	Cost	Technology
Wireless Technologies	Bluetooth	2.4 GHz ISM Band	Max. 721 kbits/s	0.1–10 m	Low	DSSS, FHSS
	IEEE 802.11g	2.4 GHz	54 Mbits/s	50–300 m (outdoors)	Low	OFDM
	IEEE 802.11b	2.4 GHz	11 Mbits/s	50–300 m (outdoors)	Low	DSSS/CCK
	IEEE 802.11a	5 GHz	54 Mbits/s	50–300 m (outdoors)	Low	OFDM, TDD
	HiperLAN2	5 GHz	54 Mbits/s	Up to 150 m	Low	OFDM
	IMT2000, UMTS	2 GHz	Max. 2 Mbits/s	30 m–20 Km	High	FDD, TDD, W-CDMA
	IEEE 802.20	Below 3.5 GHz	Up to 9 Mbits/s	20 Km	High	OFDM
	WiMax (based on IEEE 802.16-2004)	10–66 GHz/ 2–11 GHz	Up to 75 Mbits/s (with LOS) Up to 40 Mbits/s (with NLOS)	Up to 50 Km Up to 10 Km	Medium	OFDM
	IEEE 802.16d (fixed)	2–11GHz	Up to 75 Mbits/s	Up to 50 Km	Medium	OFDM
	IEEE 802.16e (mobile)	2–6 GHz	Up to 30 Mbits/s	50 Km	Medium	OFDMA
	GSM, GPRS, HSCSD, EDGE	900,1800,1900 0 MHz	9.6 Kbits/s– 384 Kbits/s	Up to 35 Km	High	TDMA, FDD
	Satellite	Up to 14 GHz	Max 144 Kbits/s	Several Kms	High	
	DAB	176–230 MHz 1452–1467.5 MHz	1.5 Mbits/s	Up to 100 Km	Low	OFDM

 GPRS: General Radio Packet Service
 OFDM: Orthogonal Frequency Division Multiplexing
 FDD: Frequency Division Multiplexing
 TDD: Time Division Duplex
 QPSK: Quadri-Phase Shift keying
 DMT: Discrete Multitone

including Bluetooth and cordless telephones. 802.11a operates in the 5 GHz band, which at this point is relatively free of interference from other electrical devices operating in this band. Although all these standards are designed for similar environments, they differ in frequency, bit rates, power requirements, and coverage.

The WLANs standardized in the IEEE 802.11 standards [IEEE 802.11b, 1999] support two modes of operation: infrastructure mode and ad-hoc mode. Of these two modes, infrastructure mode network architecture resembles the wide-area cellular networks and is of most interest to wireless Internet service providers

(WISPs). It consists of an Access Point (AP) that performs three functions:

- It implements one or more 802.11 radio interface protocols, Frequency Hopping Spread-Spectrum (FHSS), Direct Sequence Spread-Spectrum (DSSS), or Orthogonal Frequency-Division Multiplexing (OFDM).
- It implements the Carrier Sense Multiple Access with Collision Avoidance (CSMA/CA) Medium Access Control (MAC) protocol and performs packet store-and-forward to coordinate communications of Mobile Nodes (MNs) in the cell characterized by a Basic Service Set Identifier (BSSID).
- It interfaces a cell to a packet-switched network such as Ethernet, and therefore implements layer 2 packet forwarding functions such as bridging (Xu, Papavassiliou, and Narayanan 2004).

802.11b WLAN has been widely deployed in offices, homes and public hotspots such as those in airports and hotels. Any wireless data devices with a Wi-Fi certified WLAN card can potentially be connected to the Internet (or intranet) through these WLAN at a high speed, up to 11Mbps/sec. Applications for WLAN technology include wireless data access within the home and business environments.

In addition to high speed, the other advantages of WLANs include low operation cost because of operation on unlicensed spectrum, ease of deployment, and low equipment cost. However, a serious disadvantage of WLAN is the small coverage area. An 802.11b Access Point (AP) can only communicate with WLAN stations within 100–300 feet (Luo et al. 2002).

CELLULAR TECHNOLOGY EVOLUTION

The earliest wireless systems were based on analogue technology and operated in the 800 MHz range. They used the basic cellular structure of mobile communication. However, many of these systems were limited in range and

required the other party to have a similar radio. These early wireless systems gave way to the *first generation systems (1G)* in the 1980s. 1G technology limited the number of users, as each channel could only carry one conversation. The first generation technology lasted through the 1980s, when digital technology emerged, including digital signal processing techniques. *Second generation (2G)* systems were based on digital signal processing techniques and were regarded as a revolution from analogue to digital technology, and gained tremendous success during the 1990s (Jun-Zhao, Sauvola, and Howie 2001).

When the World Wide Web exploded onto the scene, it introduced the Internet to millions of people, which led to the realization that cell phones could incorporate Internet access. However, the technology of the time did not support that level of data communications, which spurred the industry into finding ways to increase the capability for data transmission. There were two products of this search—*2.5G (representing second generation telephones maximized for data communications)* and the *3G (third generation) standard* (see Figure 2).

Introduced in 2001, 2.5G telephones used a technology called digital packet switching technology. This means that each signal is broken into digital packets and each packet is sent separately. The 2.5 G extended the 2G with data switching and packet switching methods and led to hybrid communications.

The 3G (also known as *third generation*) technology involves the deployment of a new system with new services. In addition to using the digital packet switching technology, the 3G standard allows both universal access and portability across different device types. The communication speed is up to ten times faster than the speed of 2G systems and provides a multitude of services including voice, fax, Internet access, etc., with a wide range of seamless roaming.

Table 2 presents a short history of mobile telephone technology developments over the last few decades.

Researchers have already begun work on developing fourth generation (4G) wireless technologies that would support global roaming across multiple wireless and

mobile networks, such as from a cellular network to a satellite-based network to a high-bandwidth wireless LAN (Varshney and Jain 2001).

Wireless Overlay Networks

Figure 3 shows a typical structure (Inayat, Aibara, and Nishimura 2004) of wireless overlay networks. First, the networks' service areas are overlapped. For example, the General Packet Radio Service (GPRS) network acts as an umbrella network to the Wireless Local Area Network (WLAN) network. Even the different cells of the same network overlap. This overlapping can be used to reduce service disruption by simultaneously connecting to different subnets of the same access technology during transition from one network to another. Second, the networks support different data rates and cell sizes. For instance, IEEE 802.11b WLAN supports a data rate of 11 Mbits/s and GPRS a much lower data rate of about 9.6 Kbits/s. Third, because of the different characteristics of the networks involved, it is not possible to compare the signal powers received from the base stations of different networks to decide to which network to connect. Fourth, each network may offer a different level of reliability, security, quality of service, etc. As mobile hosts move across different networks, a mechanism for conveying the new IP address to the correspondent nodes is required. Also, the power consumed by the network interfaces is different for each network technology and is directly proportional to the transmitted power. For example, the Code Division Multiple Access (CDMA) transmitted power is much higher as compared to WLANs.

Currently, several wireless technologies and networks exist that capture different needs and requirements of mobile users. For high-data-rate local-area access, WLANs

are satisfactory solutions. For wide-area communications, traditional cellular networks may provide voice and data services. For worldwide coverage, satellite networks have been used extensively in military and commercial applications. Because different wireless networks are complementary to each other, their integration will empower mobile users to be connected to the system using the "best available" access network that suits their needs. Next generation wireless systems are envisaged to combine a plethora of networking technologies (see Figure 4).

Overview of 3G Mobile Networks

The name 3G, standing for third generation, is a collective term for the new communication procedures, standards and devices that will improve the speed and quality of services available on the move. The 3G takes the form of handsets that can combine the functionality of a mobile phone with that of a personal computer and a PDA. Generally, 3G devices have greater transmission abilities than their predecessors, both in terms of speed and capacity. The ITU defines 3G as any device that can transmit or receive data at 144Kbits/s or better. In practice, 3G devices can transfer data at up to 384 Kbits/s. As a comparison, Global System for Mobile (GSM) communications is up to 14.4 Kbits/s and General Packet Radio Service (GPRS) is around 53.6 Kbits/s. These are used in 2G and 2.5G respectively.

3G Standards

Two main proposed systems for 3G as recognized by the International Telecommunication Union (ITU) are as follows (Vriendt et al. 2002):

- *CDMA 2000 (Code Division Multiple Access)*: CDMA was first introduced in 1995. CDMA phones also have

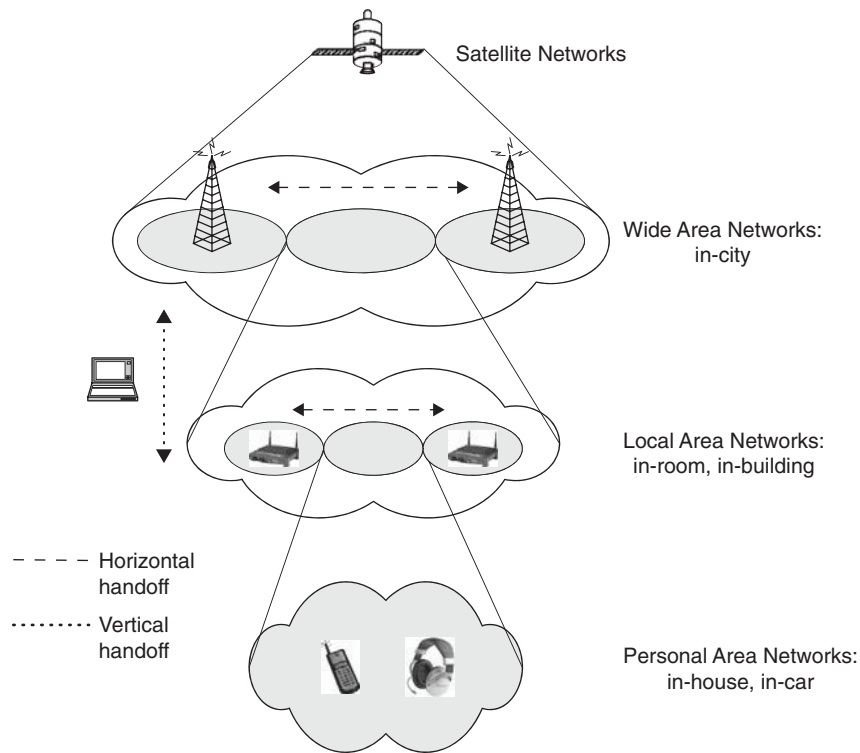

Figure 3: Wireless overlay networks

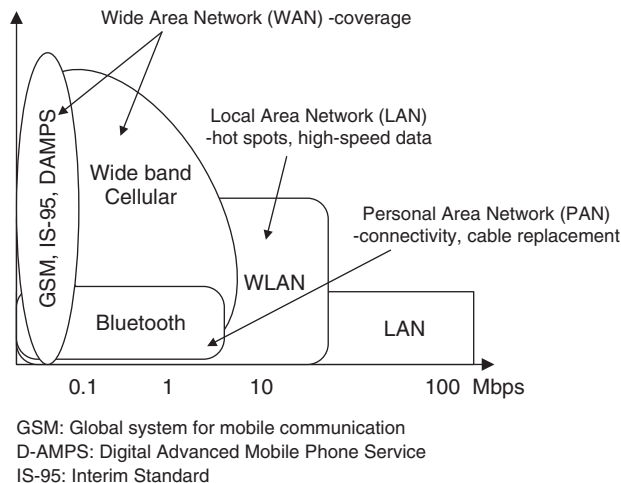

Figure 4: Link bandwidth of cellular technologies

longer standby times and also built-in reverse compatibility with earlier CDMA technology.

- *cdma2000 1x* is an evolution of *cdmaOne*, and supports packet data service up to 144 Kbits/sec.
- *CDMA 2000 1xEV-DO* introduces a new air interface and supports high-data-rate service on downlink. It is also known as High Rate Packet Data (HRPD). It requires a separate 1.25 MHz carrier for data only. 1xEV-DO provides up to 2.4 Mbits/sec on the downlink (from base station to terminal), but only 153 Kbits/sec on the uplink.

- *cdma2000 1xEV-DV*: When deployed, this will introduce new radio techniques and an all-IP architecture for radio access and core networks. It promises data rates up to 3 Mbits/sec.
- *Universal Mobile Telecommunication System (UMTS)*: UMTS is composed of two different but related modes:
 - CDMA-direct Spread: Wideband CDMA also called Frequency Division Duplex (FDD).
 - CDMA-Time Division Duplex (TDD).

FDD mode is considered the main technology for UMTS. FDD mode is derived from CDMA and uses pseudo-random codes. Separate 5 MHz carrier frequencies are used for the uplink and downlink, respectively, allowing an end-user data rate of up to 384 Kbits/sec. FDD allows the operation of asynchronous base stations. The TDD mode is Time-Division-Synchronous Code-Division Multiple-Access (TD-SCDMA). TD-SCDMA operates on low-chip-rate carriers and allows end-user data rates of up to 2 Mbits/sec.

The 3G Network Architecture

A 3G network consists of three interacting domains: a Core Network (CN), a Radio Access Network (RAN), and the User Equipment (UE). A 3G operation uses two standard suites: UMTS and *cdma2000*, which have minor differences with respect to the components they have in the RAN and the CN (see Figure 5).

The main function of the 3G core network is to provide switching, routing, and transit for user traffic. It also contains the databases and the network management functions.

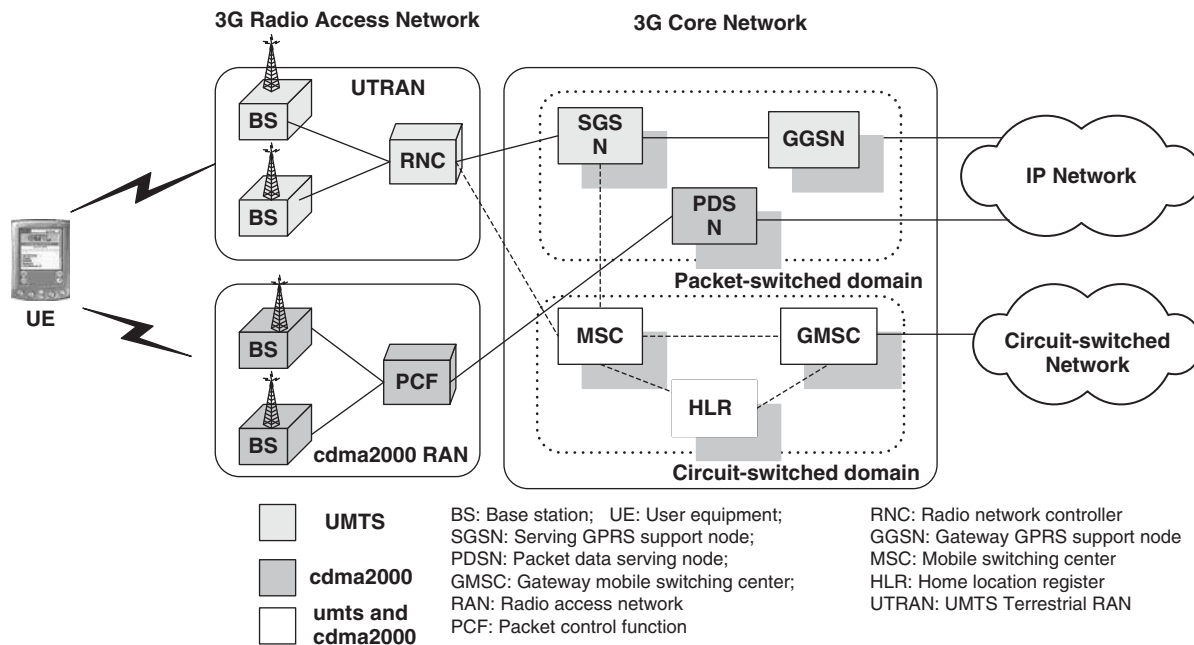

Figure 5: Components of a 3G network

The core network is divided into Circuit-Switched (CS) and Packet-Switched (PS) domains. Circuit-switched elements include Mobile Services Switching Center (MSC), Visitor Location Register (VLR), and gateway MSC. These entities are common to both the UMTS as well as the cdma2000 standards. The differences in the CN with respect to the two standards are in the PS domain. Packet-switched elements in UMTS include Serving GPRS Support Node (SGSN) and Gateway GPRS Support Node (GGSN). The cdma2000 packet-switched component is primarily the Packet Data Serving Node (PDSN). Some network elements like EIR, Home Location Register (HLR) are shared by both domains.

The main function of the MSC server is to handle call-control for circuit-based services, including bearer services, etc. The MSC server also provides mobility management, connection management, and capabilities for mobile multimedia, as well as generation of charging information. It can also be co-located with the VLR.

GGSN is the gateway to external data networks. It supports control signaling toward external IP networks for authentication and IP-address allocation, and mobility within the mobile network. GGSN provides functions for forwarding and handling user information (IP packets) to and from external networks (Internet / intranets). It also supports generation of charging information.

SGSN provides session management, i.e., mechanisms for establishment, maintenance, and release of end-user Packet Data Protocol (PDP) contexts. It also provides mobility management and supports inter-system handover within and roaming between mobile networks. SGSN also supports generation of charging information.

The PDSN incorporates numerous functions within one node. Routing packets to the IP network, assignment of dynamic IP addresses and maintaining Point-to-Point

Protocol (PPP) sessions are some of its main functions. It also initiates the Authentication, Authorization and Accounting (AAA) for the mobile station.

The radio access network provides the air interface access method for the user equipment. An UMTS RAN (UTRAN) consists of Radio Network Controllers (RNC) and Base Stations (BS) or Node-B. The RNCs manage several concurrent Radio Link Protocol (RLP) sessions with the UEs and per-link bandwidth management. It administers the Node-B for congestion control and load- ing. It also executes admission control and channel code allocation for new radio links to be established by the Node-B.

A cdma2000 RAN consists of a base station and two logical components: the Packet Control Function (PCF) and the Radio Resources Control (RRC). The primary function of the PCF is to establish, maintain and terminate connection to the PDSN. It also communicates with the RRC to request and manage radio resources in order to relay packets to and from the mobile station. It also collects accounting information and forwards it to the PDSN.

RRC supports authentication and authorization of the mobile station for radio access. It also supports air interface encryption to the mobile station.

User equipment refers to a 3G Mobile Station (MS). It can generally operate in one of the three modes of operation:

PS/CS mode: The MS is attached to both the PS domain and the CS domain, and is capable of simultaneously operating PS and CS services.

PS mode: The MS is attached to the PS domain only and may only operate services of the PS domain.

CS mode: The MS is attached to the CS domain and may only operate services of the CS domain.

The 3G architecture also includes two general interfaces: the Iu interface between the RAN and the CN, and the Uu interface between the RAN and the UE. The Radio Access Network Application Protocol (RANAP) is implemented over this interface. The user data part of the Iu interface carries end user IP traffic encapsulated in GPRS tunneling protocol-user plane (GTP-U) packets between the core network and the RAN (Miah and Tan, 2002).

MOBILE WIRELESS TECHNOLOGICAL TRENDS

Two areas of wireless technology that have experienced dramatic growth include cellular and wireless local area network technologies. In this section, we present some of the latest trends in the rate of increase of 3G subscribers, worldwide distribution of mobile subscribers, forecast of cellular subscribers, and world mobile subscribers, as shown in Figure 6, Table 3, Figure 7, and Table 4, respectively.

Cellular Subscribers

The first 3G WCDMA commercial network was NTT DoCoMo. It had 5000 test subscribers in the Tokyo area in September 2001. In March 2004, NTT DoCoMo subscribers had increased to three million (NTT Docomo 2006).

Figure 6. 3G subscribers worldwide in mid/late 2003

Table 3: Distribution of Mobile Subscribers Worldwide (Sept. 2002)

Technology	Subscribers
GSM	69.32%
CDMA	12.39%
TDMA	9.66%
Analogue	3.13%
PDC	5.49%
WCDMA	0.01%

Source: EMC via Northstream

Figure 7: Cellular subscribers: 1991–2007 forecast (source: www.theresearchroom.com)

Table 4: World mobile subscribers, 2003–2004

It is expected that the worldwide wireless market will grow to more than 2.3 billion subscribers by 2009. By 2009, WCDMA networks will be providing service for over 40% of the world's CDMA users. The total number of new subscribers in 2004–2009 is expected to be 777.7 million worldwide.

Wireless LAN (WLAN) Subscribers

In the United States, we expect that more than 21 million Americans will be using public Wireless Local Area Networks (WLANs) by the year 2007 (ClickZ 2002). This is mainly because users are attracted by the cheap and super fast remote Internet access provided in airports, shopping malls, coffee bars, and hotels. Public WLAN services enable users to hook up their laptops and PDAs to their Internet Service Providers (ISPs) or company intranet at speeds of up to 11 Mbps/s. The number of hot-spot locations in the U.S. is expected to grow from 3,700 this year to 41,000 by 2007. This, in turn is expected to generate over \$3 billion in service revenues (ClickZ 2002).

The development of the WLAN market has been spurred on by the industry-wide adoption of a common technical platform based on the IEEE 802.11 standard. There is a rapid increase in the number of devices such as PDAs and

laptops (forecast to top 91 million in the next five years), that are now being shipped with cards already installed that can make use of public WLAN networks (see Figure 8). According to recent research, the most notable issue to be resolved is the ability of public WLAN operators to provide wide coverage for potential users. These operators need to pursue roaming agreements with each other to minimize the cost of deploying access gateways in every possible hot-spot location. The distribution of WLAN hot-spot locations worldwide in recent years is shown in Table 5.

For the WLAN market to accelerate, it is imperative for service providers to offer better location information and network detection software as part of well-presented service propositions with appropriate security and pricing. The impact WLAN services will have on the cellular phone market remains unclear. Analysis predicts that by 2007 the public WLAN market will equate to about 25 percent of mobile data service revenues and could cannibalize up to 7 percent of cellular data operator revenues in the United States (ClickZ 2002).

Some of the most popular Wi-Fi Hot Spot operators and their associated number of wireless access points are given in Table 6.

The IEEE 802.16 (Chung, Chang, and Lin 2005) family of standards and its associated industry consortium, WiMax (WiMax 2004), promises to deliver high data rates over large areas to a large number of users in the near future. This exciting addition to current broadband

options such as Digital Subscriber Line (DSL), cable, and Wi-Fi, promises to rapidly provide broadband access to locations in the world's rural and developing areas where broadband is currently unavailable, as well as competing for urban market share [3G UK] (see Figure 9).

It is expected that by the end of 2009, there will be more than 7 million subscribers worldwide using broadband wireless services based on 802.16REd technology, the fixed flavor of WiMax (WiMax 2004). Future wireless networks are envisioned to support different wireless communication technologies such as WPANs, WLANs, WMANs, 3GPPP, and sensor networks (Weber 2000). Today, it would be very rare to expect a single device to operate in all wireless environments. Even in situations in which a single device can establish basic connectivity in multiple wireless networks, users are faced with multiple and incompatible technologies for access control, signaling, and data transport.

INTERNETWORKING ARCHITECTURES FOR WLANS AND CELLULAR NETWORKS

A 3G wireless system such as UMTS can provide mobility over a large coverage area, but with relatively low speeds of about 144 Kbits/sec. WLANs provide high speed data services (up to 11 Mbits/sec with 802.11b and 54 Mbits/

sec with 802.11a) over a geographically smaller area. An integrated network combines the strengths of each, resulting in a wide-area system capable of providing users with ubiquitous data service ranging from low to high speed in strategic locations. Thus, 3G/WLAN integration provides users with a high-speed wireless connection as well as anytime anywhere connectivity. The integration of the two technologies implies that a seamless roaming mechanism between these heterogeneous networks needs to be present. For example, a mobile node has an ongoing session through a WLAN network. As the node moves out of the coverage of the WLAN, it should seamlessly switch to the 3G network without requiring any user-intervention or affecting the ongoing session. This handover should not be perceived by the end user. Similarly, session flow should continue through the WLAN on acquiring the WLAN coverage again. This transparent mobility between the two access networks provides users with continuous service as well as with high-speed coverage in certain areas.

Hence, WLANs are generally used to supplement the available bandwidth and capacity of a 3G network in

hotspot area such as railways and airports with high-traffic densities, without sacrificing the capacity provided to cellular users. It provides support for data-intensive applications and enables smooth online access to corporate data services, while still allowing users to roam from the private pico-cell network to the wide area 3G network.

We briefly present a comparison of UMTS and WLAN technologies in Table 7.

To reap the benefits of both cellular and WLAN technologies, a standardized mechanism for internetworking between these access technologies is required to enable seamless mobility while a user roams across different networks. Several approaches have been proposed for internetworking between WLANs and cellular 3G networks.

Tightly Coupled Internetworking

In the case of the tight-coupling architecture (Hongyang Chen and Jiang 2003), the WLAN network is deployed as an alternative Radio Access Network (RAN) and connects to the 3G Core Network (CN). From the CN's point of view, the WLAN is considered like any other 3G Routing Area

Table 7: UMTS-WLAN Comparison

UMTS (3G)	WLAN
Maximum data rate only 384 Kbits/sec while moving and up to 2 Mbits/sec stationary	Maximum data rates of 11Mbits/sec, 20 Mbits/sec, or 54 Mbits/sec.
Mature mobility management handling including handover and roaming (based on GSM)	Many unresolved issues regarding mobility management
500-meter radius in urban areas	50-meter radius in urban areas

(RA) in the system. In other words, the 3G CN does not really identify the difference between an RA with WLAN technology and one with 3G technology.

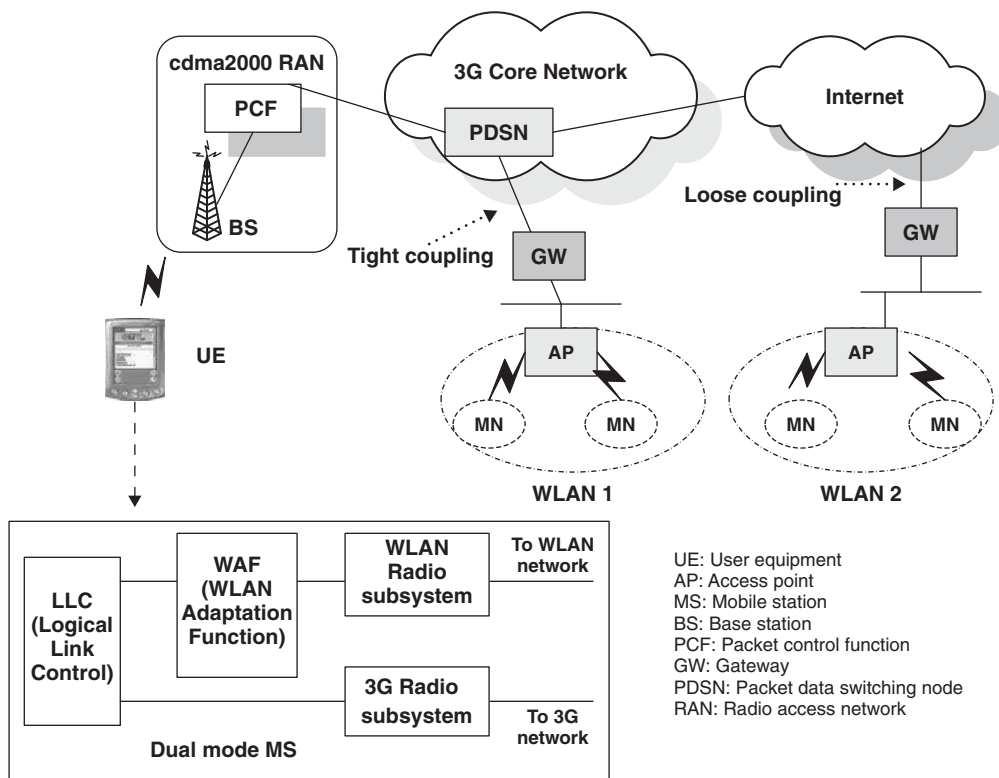

The main element in the tight coupling approach (Salkintzis 2003) is a gateway that is connected inbetween the WLAN and the 3G core network's Packet Data Serving Node (PDSN). The PDSN aggregates the data traffic from multiple RNCs and interfaces the RAN to the packet-switched network. The main function of the gateway is to provide a standardized interface to the 3G core network and hide the WLAN details. In this approach, the 3G protocols for signaling, transport, billing, authentication, etc. are fully reused (see Figure 10).

When a Mobile Station (MS) is outside the WLAN area, its WLAN interface is in passive scan mode; that means, it scans a specific frequency band and searches for a beacon signal. When a beacon is received, the Service Set Identifier (SSID) may be checked and compared against a preconfigured SSID. The SSID serves as a WLAN identifier that can help the MS to attach to the WLAN to which they have subscription.

The MSs are considered to be dual mode; i.e., they have two radio interfaces, one for 3G access and another for WLAN access. Seamless mobility is achieved by means of an RA Update (RAU) procedure which is a core mobility management function. When an MS enters a WLAN, a RAU procedure takes place and subsequent signaling and user data are carried over the WLAN interface. Similarly, when an MS exits a WLAN, another RAU procedure occurs and the 3G interface is enabled to carry further data and signaling.

The WLAN Adaptation Function (WAF) is a key component present in the MS which identifies when the WLAN radio subsystem is enabled and informs the LLC layer, which subsequently redirects signaling and data through the WLAN. The WAF provides switching between the two interfaces. Whenever, the MS is outside the WLAN area, the LLC Packet Data Units (PDUs) are transported over the 3G interface. However, when the MSs enter the WLAN coverage, the LLC PDUs are transmitted over the WLAN interface. The switching as performed by the WAF is completely transparent to the user.

Some of the benefits associated with tight coupling include: faster handoff speed, service continuity with almost no disruption while changing access networks, and

**Figure 10:** Tightly coupled versus loosely coupled inter-networking

high security provided through the reuse of 3G security mechanisms. Drawbacks of the tight coupling approach include:

- It requires the same operator to own both the WLAN network, as well as the 3G network, because the 3G core network directly exposes its interfaces to the WLAN network.
- It does not make feasible the integration of independently operated WLANs and 3G networks without explicit connectivity to the 3G core network.
- It requires complex and expensive reconfiguration of the 3G core network and WLAN gateways.
- It makes it mandatory to use 3G-specific authentication mechanisms for authentication on WLANs, forcing WLAN providers to interconnect to 3G carriers' SS7 network to perform authentication procedures.

Loosely Coupled Internetworking

In the case of the loose-coupling approach (Buddhikot et al. 2003), the WLAN gateway connects to the Internet and does not have any direct link to 3G network elements such as the PDSNs, etc. The approach is referred to as "loosely coupled" because it completely separates the data paths in 3G and WLAN networks. In other words, in contrast to tight coupling, the WLAN data traffic does not pass through the 3G core network but goes directly to the IP network (Internet). In this approach, different mechanisms and protocols can handle authentication, billing, and mobility management in the 3G and WLAN portions of the network. However, for seamless operation to be possible, these mechanisms and protocols have to interoperate. One way of achieving this is for the WLAN gateway to support mobile IP functionalities (Perkins, 2002) to handle mobility across networks as well as Authentication, Authorization, and Accounting (AAA) services to internetwork with the 3G's home network AAA servers. There are several benefits associated with loose coupling:

- It permits independent deployment and traffic engineering of WLAN and 3G networks.

- It does not require extensive capital investments because the 3G providers can benefit from other providers' WLAN deployments.
- It provides widespread coverage through roaming agreements with many partners.
- It allows a wireless Internet service provider to provide its own public WLAN hotspot, interoperate through roaming agreements with public WLAN and 3G service providers, or manage a privately installed enterprise WLAN.

However, the loose coupling approach also suffers from various drawbacks, including higher handoff delays compared to tight coupling and the possibility of session interruption during handoff (see Table 8).

Gateway Approach for UMTS/WLAN Internetworking

The gateway approach for WLAN/3G internetworking provides seamless roaming between UMTS and WLAN networks (Tsao and Lin 2002). The two networks operate independently but offer roaming services to their customers. A new logical node, called Virtual GPRS Support Node (VGSN) is designed to connect UMTS and WLAN core networks. The node exchanges necessary information between networks, converts signals, and forwards the packets for roaming users (see Figure 11).

When a Mobile Station (MS) moves from a 3G network to a WLAN, it performs certain handover procedures. The MS first tries to obtain the VGSN address. It does so by sending a Dynamic Host Configuration Protocol (DHCP)_DISCOVER message in the WLAN network. The VGSN responds to the MS with its IP address. After the MS receives the VGSN address, it sends a Routing Area Update (RAU) to the VGSN, using its original IP address on the 3G network. Then the VGSN sends another update request to the Gateway GPRS Support Node (GGSN) of the 3G network asking it to change its Serving GPRS Support Node (SGSN) address. The SGSN and GGSN are components of the 3G network that provide session management and interfacing to external packet data networks respectively. Then the VGSN simulates an SGSN of the 3G network.

Table 8: A Comparison of Loose Coupling and Tight Coupling

	Loose Coupling	Tight Coupling
Handoff latency	High	Low
Connectivity	Chance of service disruption during handoff	Seamless connectivity during all times
Network ownership	Independent ownership of 3G and WLAN networks permitted	Single ownership of 3G and WLAN networks
Security	Medium security	High security through the reuse of 3G security mechanisms
Deployment cost	Cheap	Expensive

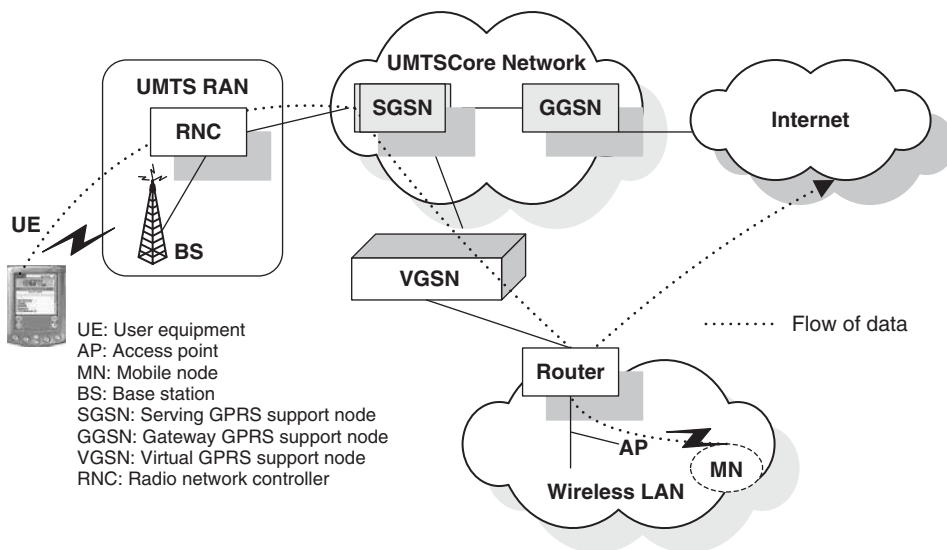

Figure 11: The gateway Internet-working approach

On receiving an update from the VGSN, the GGSN becomes aware that the MS has moved to a WLAN. The VGSN now temporarily plays the role of an SGSN. All packets destined for the MS now go through the VGSN instead of the old SGSN. The packets from the MS to the Internet can be sent out using the old IP address of the 3G network if the WLAN does not perform filtering of non-WLAN IP addresses. If the WLAN applies the filtering procedure, then the packets need to go through the VGSN to the Internet. Some benefits of the gateway approach include: the two networks are allowed to operate independently, packets for roaming users go through the VGSNs to Internet and experience low packet loss and delay, and the approach does not need to use Mobile IP.

UMTS-WLAN Internetworking with Mobile IP

The Mobile IP internetworking architecture (Tsao and Lin 2002) considers 3G and WLANs as *peer-to-peer*

networks. If User Equipment (UE) decides to move from a 3G network to a WLAN network, it needs to disable its 3G protocols and use the IP stack. In order for the UE to use the same IP address that it used in the 3G network, i.e., be accessed via the old IP address, then mobile IP is used. Foreign agents and home agents are installed in the WLAN Access Router (AR) and the GGSN of the 3G network routers can tunnel and forward the data packets.

When a UE moves from the 3G network to the WLAN network, the 3G network detaches the UE as it fails to receive the periodical Route Area (RA) update message from the UE. The UE then sends a *standby* message to the SGSN, which helps the UE to reattach to the 3G network after it moves back. Once in the WLAN, the UE can send an *Agent Solicitation* message to locate the local FA. Once the UE receives a reply from the local FA, it then sends a *Registration Request* to the HA. After the Care-of-Address (CoA) in the HA is updated, the packets sent to the home network (3G) will be forwarded to the visited network (WLAN) (see Figure 12).

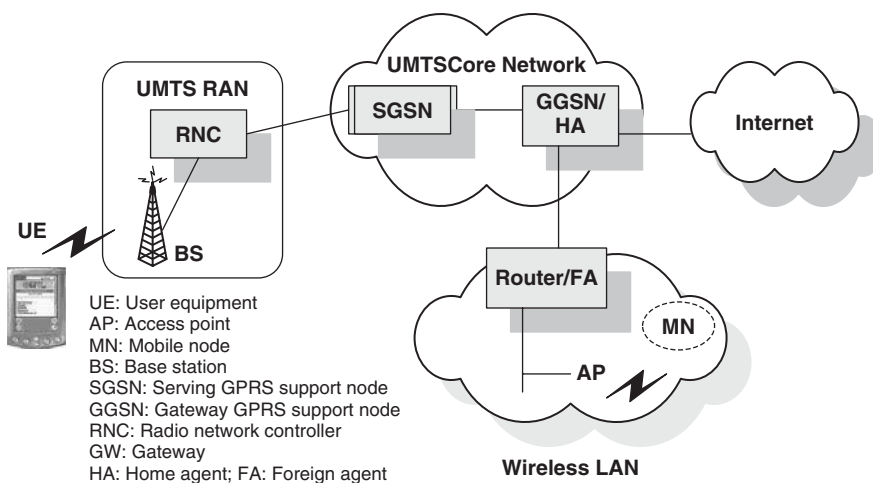

Figure 12: Architecture for mobile IP approach

Although the mobile IP approach allows easy deployment strategies, it suffers from long handover latency (Akyildiz et al. 2004) and might not be able to offer real-time services and applications.

Enterprise-oriented Integration of Cellular Networks with WLANs

The objective of an enterprise-oriented solution is to provide a secure mobile networking method for corporate users to connect their computers to office networks through cellular networks and various WLANs, including office WLAN, home WLAN, and public WLAN, where the connection is expected to remain alive when a user moves between WLAN and a cellular network.

Luo et al. propose an enterprise-oriented WLAN/3G integration solution called the Internet Roaming system (Luo et al. 2002). It is an IP-based corporate network architecture that provides seamless internetworking across office WLAN, home WLAN, public WLAN, and 3G cellular network for corporate wireless data users. The architecture consists of four components, namely, the Internet Roaming Agent (IRC), the Secure Mobile Gateway (SMG), the Secure IP Access Gateway (SIA), and the Virtual Single Account Server (VSA). The IRC is a special client tool installed on a user's computer equipped with a WLAN adapter and a cellular data modem. It provides a secure mobile IP connection from the user's computer to the corporate network, transparent to the operating system of the user's computer. The SMG is a mobile IPsec gateway installed on the corporate core network facing the Internet. It works with the IRC to maintain a secure mobile IP connection when the user's computer is connected on the Internet through a home WLAN, a public WLAN, or a cellular network. The SIA server is a special security gateway installed on the corporate intranet where the office WLAN is installed. It works with the IRC to assure the security of the office WLAN while keeping compatibility with firewalls for user computers. The VSA server manages the IRC, SMG, and SIA servers.

PERFORMANCE EVALUATION OF UMTS-WLAN INTEGRATION AT SGSN AND GGSN NODES

Via simulations using OPNET, we evaluated two inter-networking architectures to interoperate the 3G (UMTS) and WLAN networks by connecting them at two strategic points: the SGSN node and the GGSN node as shown in Figure 13.

UMTS-WLAN Integration at the SGSN Node

When the UMTS and WLAN networks are connected through the SGSN node, the WLAN network does not appear to the UMTS core network as an external packet data network. Instead, it simply appears as another radio access network. The WLAN AP in this case needs to have the capability of processing UMTS messages. Thus, whenever a Mobile Node (MN) in the WLAN network wants to exchange data with the UMTS UE, it first needs to undergo the GPRS Mobility Management (GMM) attach procedure to notify the SGSN of the location on the communicating node and also to establish a packet-switched signaling connection. The WLAN AP is responsible for sending these request messages to the SGSN on behalf of the WLAN MN. The GMM attach procedure is a three-way handshake between the MN, RNC, and the SGSN. Upon completion of this procedure, the WLAN MN is authenticated into the UMTS network.

UMTS-WLAN Integration at the GGSN Node

In this type of integration, whenever an MN in a WLAN network wants to communicate with a UE in the UMTS network, it does so through the GGSN node. The UE in the UMTS network first activates the Packet Data Protocol (PDP) context that it wants to use. This operation makes the UE known to its GGSN and to the external data networks, in this case, the WLAN network. User data is transferred transparently between the UE and the WLAN network with a method known as encapsulation and

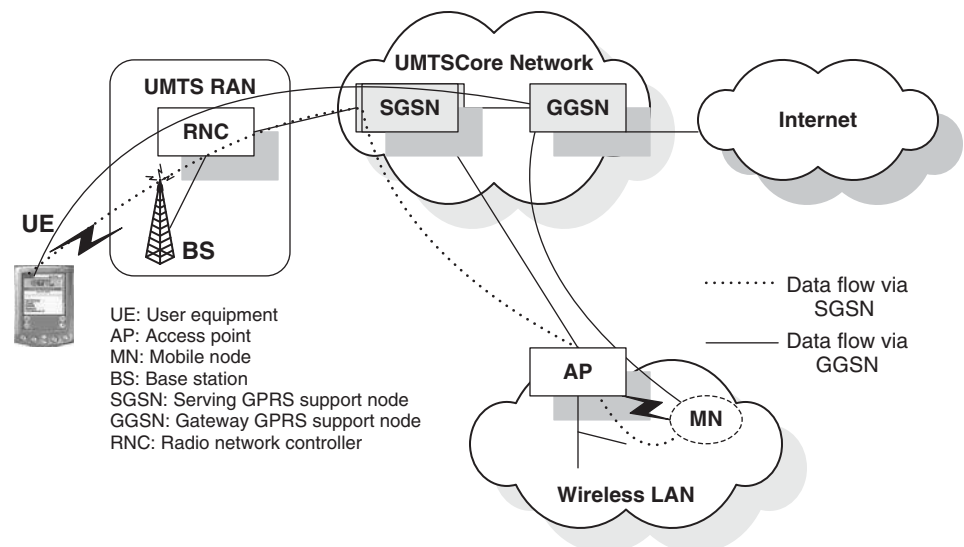

Figure 13: 3G-WLAN integration
a) SGSN b) GGSN

tunneling. The protocol that takes care of this is the GPRS Tunneling Protocol (GTP). For this kind of internetworking configuration, the WLAN AP is a simple 802.11b access point and does not need to process UMTS messages.

Simulation Testbed

A network simulation model was constructed using OPNET 10.0.A (OPNET 2006). OPNET is a discrete event simulator with a sophisticated software package capable of supporting simulation and performance evaluation of communication networks and distributed systems.

The simulation environment we used had a UMTS network connected to a WLAN network. The UMTS network was composed of the RAN and a packet-based CN with SGSN and GGSN nodes. The WLAN network is composed of 802.11b wireless MNs configured in Infrastructure Basic Service Set mode. In the GGSN integration case, a simple WLAN access point was used, while in the SGSN integration case, a different access point with additional capability of processing UMTS messages was employed. The goal of the simulations was to compare the delays involved when user data is exchanged between the UMTS and WLAN networks connected via two methods, namely GGSN and SGSN. Different types of traffic were generated using three different applications, including Voice

over IP (VoIP), FTP, and HTTP (web browsing) as shown in Table 9. These applications correspond to the various UMTS QoS classes—conversational class for real time flows such as VoIP, interactive, and background classes for FTP and HTTP respectively. Packet delay, jitter, upload, and download response times were measured. Other parameters associated with each application are summarized in Table 9.

Simulation Results and Discussion

Simulations performed for both UDP and TCP flows are presented. For the UDP flow (VoIP traffic), end-to-end packet delays and jitter were measured. For TCP flows (FTP, HTTP) the upload/download response times were measured.

Figure 14a shows the simulation run-times corresponding to the average file upload times experienced when transferring files of various sizes between the UE and the WLAN MN under two different integration scenarios. In Figures 14b and 15a, the average delay and jitter for voice are presented. It is observed that both delay and jitter values are much lower in the GGSN case. Similarly, Figure 15b shows the response time to access a web page of the size of 3000 bytes. As Figure 15b illustrates, the page response time is initially high and then decreases as

Table 9: Descriptions of Various Applications Tested

Application	QoS Class	Measurement (seconds)	Size	Protocol
FTP	Background	File download time	100–1000 Kilobytes	TCP
FTP	Background	File upload time	100–1000 Kilobytes	TCP
GSM encoded voice	Conversational	End-to-end delay	33 Bytes	UDP
GSM encoded voice	Conversational	Jitter	33 Bytes	UDP
HTTP Web browsing	Interactive	Page response time	3000 Bytes	TCP

Figure 14: Application response times: a) FTP upload b) VoIP delay

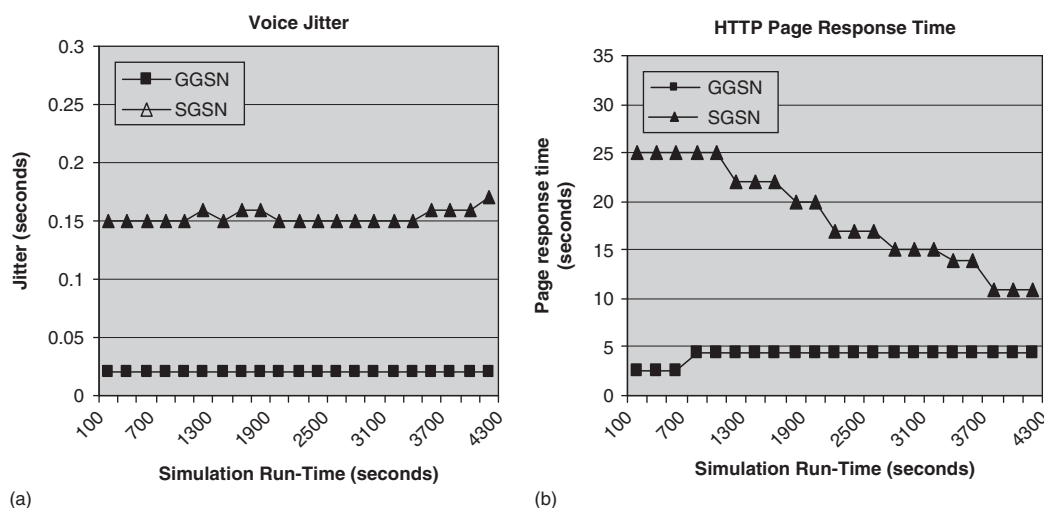

Figure 15: Application response times: a) VoIP jitter b) HTTP page response time

the simulation progresses. We speculate that this reduction in the page response time may be because the Web server's cache is initially empty and the first few page requests cause the page to be fetched from the disk, resulting in a high response time. As more requests are generated with time, the cache is being filled, increasing probability that one or more requests can be satisfied by the cache, thereby reducing the overall page response time.

The simulation results reveal that the application response time (delay) is consistently higher in the case in which the UMTS and WLAN networks are connected through the SGSN node, as compared to the case in which the two networks are connected at the GGSN. This higher response time can be attributed to the additional processing time required at the WLAN access point in the first case. When the two networks are connected at the SGSN node, the WLAN access point performs the functions of an RNC as well as a WLAN AP. Therefore, it has to perform the additional initialization steps to authenticate the WLAN MN to the UMTS network (GMM attach procedure and PDP context activations). When integration is done at the GGSN node, the WLAN AP is a simple 802.11b access point and does not require any special capabilities to process UMTS messages. Data packets are transferred between the UE and the WLAN network using encapsulation by the GPRS tunneling protocol. This reduces the packet latency because there is no additional delay due to UMTS initialization procedures or packet conversions.

The advantages of using the SGSN integration scheme include the reuse of UMTS authentication, authorization, and accounting (AAA) mechanisms; usage of common subscriber databases and billing systems; increased security features (because the UMTS security mechanisms are reused); and the possibility of having continuous sessions as users move across the two networks. The handoff in this case is very similar to an intra-UMTS handoff because the WLAN AP appears as another RNC to the SGSN node. In the case of GGSN integration, because the WLAN is considered to be an external network, different billing and security mechanisms are needed. Service disruption is also possible during a handoff from one network to another.

VERTICAL HANDOFF MANAGEMENT TECHNIQUES FOR HETEROGENEOUS WIRELESS NETWORKS

Several techniques have been proposed to perform handoffs during roaming across heterogeneous wireless access networks and most of these techniques operate at different layers of the protocol stack. In addition, most of the proposed handoff approaches are based on modification of the Mobile IP protocol and are implemented at the network layer (McNair and Fang 2004; Fan, Ni, and Esfahanian 2002; Badis and Khaldoun 2004; and Sharma et al. 2004). Other handoff strategies include SIP-based handoff (operating at the application layer) (Banerjee et al. 2004), and Stream Control Transmission Protocol-based (SCTP-based) handoff (operating at the transport layer) (Li et al. 2004). These are also other schemes for handoff management that have recently been proposed to achieve seamless mobility for TCP connections (Kim and Copeland 2003; Vidales et al. 2004). Other types of handoff schemes are based on efficient energy consumption of network interfaces (Wen-Tsuen, Jen-Chu, and Hsieh-Kuan 2004; and Minji et al. 2004). An in-depth discussion on the detailed operations of each of these protocols is beyond the scope of this paper. However, we briefly outline the purpose of each of the mobility protocols in Table 10.

We present a review (as shown in Table 11) of the various vertical handoff approaches that have been proposed over the last few years, based on features such as the type of handoff (mobile-controlled or user-controlled) basis (Inayat, Aibara, and Nishimura 2004) for handoff decision, and handoff latency. We found that most of the approaches proposed exploit handoff schemes that are mobile-controlled (i.e., handoff decision is made by the mobile node independently). Moreover, most of the handoff techniques use a simple handoff decision method (usually based on one or two factors only) and lack support for intelligent handoff decision strategies based on multiple factors such as cost, security, user preferences, and application requirements, all of which have been important factors affecting service delivery while moving over hybrid wireless networks.

Table 10: Mobility Protocols for Seamless Roaming Across Heterogeneous Wireless Access Networks

Technology	Main Function
Mobile IP	Enables mobile devices to maintain their IP addresses while moving between different networks
Mobile IPv6 (Johnson 2004)	Provides enhanced features to Mobile IP for optimizing the mobility process
Mobile Stream Control Transmission Protocol (mSCTP)	Transport layer solution that provides seamless roaming capability across different networks
Session Initiation Protocol (SIP)	Application layer solution that provides both personal and terminal mobility across different networks

Table 11: A Comparison of Vertical Handoff Approaches

Handoff Approach	Type of Handoff	Handoff Latency	Basis for Handoff Decision	Description
HOPOVER (Fan, Ni, and Esfahanian 2002)	Mobile-controlled	Moderate	Reception of WLAN signal	Addresses the problem of high handoff frequency that cannot be handled by traditional Mobile IP
WISE (Minji et al. 2004)	Mobile-assisted	Low	Energy consumption of interfaces, network load	An energy-efficient interface selection method for vertical handoffs in tightly integrated systems
Hierarchical method (Badis and Khaldoun 2004)	Mobile-controlled	Low	Reception of WLAN signal	A fast handoff scheme that reduces upward vertical handoff latency, packet loss and disruption
OMNICON (Sharma et al. 2004)	Mobile-controlled	Moderate	Reception of a strong WLAN signal	Improves Mobile IP handoff by supporting packet scheduling and buffering
TCP-based method (Kim and Copeland 2003)	Mobile-controlled	Low	Reception of WLAN signal strength and velocity	Improves performance of TCP connections during vertical handoffs
SCTP-based (Li et al. 2004)	Mobile-controlled	Moderate	Reception of WLAN signal	Improves handoff delay and throughput using the multihoming capability and dynamic address configuration of SCTP
SIP-based (Banerjee et al. 2004)	Mobile-controlled	High	Reception of WLAN signal	An application-layer solution for vertical handoffs in heterogeneous networks
Adaptive method (Wen-Tsuen, Jen-Chu, and Hsieh-Kuan 2004)	Mobile-controlled	Low	Energy consumption of interfaces, and QoS offered by networks	An effective system discovery method to reduce power consumption during vertical handoffs

END-USER TERMINAL SUPPORT FOR HETEROGENEOUS WIRELESS NETWORKS

To support the ever-increasing heterogeneity of current and future wireless access networks, we need to design and develop end-user terminals that will provide the capability to access diverse networking technologies. Current multimode devices are of two different types:

- The first type includes those devices capable of supporting multiple wireless access systems by incorporating several network interface cards and the appropriate software for switching between these network interfaces. These devices are often referred to as “multimode terminals.”
- The second type includes those devices which use adaptable software modules operating on a generic, reconfigurable hardware platform consisting of Digital Signal Processors (DSPs) and general purpose microprocessors, used to implement radio functions such as generation of transmitted signal (modulation) at the transmitter and tuning/detection of received radio signals (demodulation) at the receiver. Such devices are referred to as Software-Defined Radios (SDRs) (Dillinger, Madani and Alonistioti 2003).

Multimode Wireless Terminals

Multimode wireless terminals (McCann et al. 2006) are devices that can support multiple radio access technologies and allow the reception of data over multiple system bearers with different characteristics. An intelligent multimode terminal should be able to decide *autonomously* the active interface that is “best” for an application session and to select the appropriate radio interface as the user moves in and out of the vicinity of a particular technology. The decision regarding the switching of the interface and the handoff of the active sessions to the newly active interface may be decided based on user preference setup (which may also be referred to as ‘user policy’) on the multimode terminal regarding the interface usage. For example, if the user has set up some preference to indicate that the PDA should default to using the fastest and cheapest interface available, the terminal will switch to the WLAN interface (assuming this is the cheapest interface available at that moment) whenever the PDA enters into the WLAN coverage area. However, the multimode terminal must also take into account other factors such as the QoS requirements of applications, cost, and other factors in selecting the most appropriate wireless network. It is worth pointing out some of the characteristics that future multimode terminal designs will be expected to support:

1. The terminal should operate with minimal inputs from the user. From a user perspective, it is preferable to carry out these decisions in an automated way rather than having to query the user every time a new interface becomes available, or an old interface disappears.

2. The terminal should be able to handle session handoffs from one interface to the other based on user policy.
3. Radio access interfaces selection should be based on user policy and other factors, including application QoS requirements and information about the network.
4. The requirements of applications need to be determined to help decide whether applications would benefit from a switch of interfaces.
5. Traffic should be smoothly transferred while the active interface is changed in a way that is transparent to the user (i.e., as seamlessly as possible).

Deployment Issues for Multimode Terminals

1. **Network Detection:** A multimode terminal must be able to detect the availability of a new network (example WLAN connectivity). For some interface technologies, resources are not exhausted even if the interface is permanently on and scanning for network access coverage continues for a long period of time. In the case of IEEE 802.11 WLANs, continuous scanning for the presence of other networks is not feasible because of the amount of power needed to keep the interface actively scanning for access points. So the issue that arises is how to activate the WLAN interface only when in the vicinity of a hotspot. Currently, this activation of the interface is left to users who manually enable their WLAN card when in a hotspot. However, because one of the multimode terminal requirements is to minimize user interaction, a desirable goal in this case would be to automate this process. One solution that would achieve this result would be to advertise the presence of nearby services (or coverage of other technologies) via the currently active interface. For example, the presence of a hotspot could be sent via GSM, which would then activate the WLAN interface automatically.
2. **Network Information:** Finding out information about networks to support interface selection decisions is another relevant issue. For example, if a user has specified that the mobile terminal should default to using the cheapest connection, then for the terminal to be able to decide on the cheapest connection, some charging information must be made available by the network. Service providers may choose to advertise certain pricing information, allowing the prices of the different networks to be compared. This information also needs to be formatted or standardized between operators so that it is easy to compare. Other information may also be advertised, such as authentication methods which allow the terminal to determine in advance if switching access networks is required. We need to investigate how to make this information available to mobile users.

To support access to different types of network technologies, it is essential to develop multimode terminals’ versatile capabilities that can dynamically adapt to various wireless technologies that differ in their operating frequencies, data rate, and access technology. In addition,

such multimode devices should be 'smart' enough to shift the responsibility of network selection from the user to the terminal.

INTERNETWORKING CHALLENGES OF FUTURE HETEROGENEOUS WIRELESS NETWORKS

Significant challenges need to be addressed before true internetworking and seamless integration among heterogeneous wireless access systems become a reality. The strong convergence on IP technology is a step forward towards those goals and makes IP the core networking protocol that effectively bridges various wireless communication technologies with high flexibility. However, with user requirements such as mobility, bandwidth, and access range, more research is needed on internetworking design architectures and protocols.

Several outstanding issues (Suk, Kai, and Hau 2003) still need to be resolved to deploy and implement a complete internetworking solution for transparent, seamless, secure roaming across future heterogeneous wireless networks. However, current technologies such as handoff management techniques do not yet provide adequate support. As a result, mobile users of hybrid wireless networks are often required to restart applications to connect to a new point of attachments. In a wireless environment, it is common to go out of range or coverage (for a few seconds or up to a minute) and handoff between subnets takes a finite amount of time (while handling mobility); it is necessary to ensure that the application session state be maintained. Mobile users want fast Internet access and seamless roaming capability without the complexities of configuring devices, inputting authentication parameters, entering and changing user preferences, updating parameters, and receiving bills from multiple service operators (Kim and Copeland 2003). User demand for new services featuring seamless roaming, hassle-free authentication, and configuration requires the support of new designs and protocols that will simplify device configuration and authentication in order to make seamless roaming possible.

To summarize, we briefly discuss some of the main research issues that are expected to play a fundamental role in the design and implementation of future architectures and protocols in the future:

- **Multimodality:** To enable access to different types of wireless network technologies, we need to develop multimode terminals that are capable of adapting to various technologies with different characteristics such as frequency of operation and data rates. In addition, these devices should be "smart" enough to make intelligent decisions on interface selection in a way that is transparent to the mobile user during roaming across different wireless networks.
- **Efficient and Seamless Roaming:**
 - **Detection of Network Coverage:** Mobile devices must be able to easily and efficiently detect the presence of a new network coverage area through processing

signals sent from different wireless systems, which differ in access protocols and are incompatible with each other.

- **Selection of the Most Appropriate Access Network:** Wireless networks differ in terms of various factors, and the task of selecting the most appropriate network is complex with respect to the needs and services of an end-user.
- **Handoffs:** Moving across various network technologies presents the need to design intelligent and efficient handoff techniques with minimum latency and packet losses. Handoff management techniques should allow mobile users to roam among multiple wireless networks in a manner that is completely transparent to applications and disrupts connectivity as little as possible. In addition, in hierarchically structured wireless systems, the choice of the best wireless network for location and handoff management poses a significant challenge because different overlay levels might have widely varying characteristics. Moreover, in traditional mobile systems, only horizontal handoff has to be performed whereas in next generation wireless-access systems, both horizontal and vertical handoff should be performed.
- **Quality of Service (QoS) Requirements:** Next generation wireless systems will consist of various access technologies with differing parameters interconnected with a common IP-backbone. Mobile terminals will typically host various types of multimedia applications. These applications have varying requirements, which may not be satisfied by the underlying best-effort IP framework. Providing adequate QoS support including bandwidth, delay, reliability, perceived quality, and costs in a heterogeneous mobile computing environment remains a significant challenge. Mobility management in such environments also introduces new issues such as timely service delivery and QoS negotiation during inter-system handoff. The main problem in providing QoS in a mobile environment is the integration of QoS and mobility management—the ability to provide the same level of quality to the packet flow during and after the handoff. To the best of the authors' knowledge, none of the available technologies today allow full seamless IP mobility with full end-to-end QoS support. This end-to-end QoS issue (spanning over different wireless networks) becomes even more challenging given the broad range of QoS mechanisms available for each individual network. As a result, it becomes almost impossible for an application designer to select a single QoS framework that is supported across different types of networks. We need to investigate novel QoS approaches that will efficiently support end-to-end QoS over hybrid wireless networks.
- **Security:** The existence of heterogeneous wireless access systems makes end-to-end security support challenging during host mobility. This requires the development of novel, adaptive security mechanisms and protocols.
- **Billing and Pricing:** The existence of multiple networks gives rise to the presence of several network operators. To eliminate the need for separate bills associated with

specific wireless provider, we need to investigate and deploy new billing (Globalbilling 2004) and accounting procedures and mechanisms for end-users accessing various types of networks during typical sessions.

- **Context Information Transfer:**

- **Context Transfer:** Handoff in heterogeneous environments requires the transfer of contextual information (Kempf 2002) for information flow between the mobile node and the network. Context transfer is designed to allow access routers to exchange state information regarding a mobile node's packet treatment. A context transfer protocol aims to minimize the impact of transport/routing/security-related services on the handoff performance. When a mobile node moves to a new subnet, it needs to continue services that have already been established at the previous subnet. Such services are called "context-transfer candidate services" (Georgiades and Tafazolli 2004) and include information such as Authentication, Authorization and Accounting (AAA) profiles, IP Security (IPSec) states, QoS policy, and others. A context-transfer protocol needs to be developed to allow fast re-establishment of context-transfer candidate services when a new network is encountered, to enable seamless operation of application streams during user mobility.

- **Security of Context Transfer:** Sensitive context information must be protected to preserve user privacy and maintain security. The security context shared between different domains represents a level of trust between them. If context is transferred to another intermediate device, whether in the same domain or different domains, ideally, the same level of trust must be in place as between the intermediate device and the authentication server. Network mobility management can be optimized if contexts are transferred securely from one entity to another.

- **Inter-service Provider Compliance:** An effective handoff scheme is required on existing network infrastructures consisting of different networks owned by different service providers and should not require major modifications to the underlying networks.

CONCLUSION

Wireless technology has had a tremendous impact on our society. Wireless networks continue to be deployed at a high rate in different fields of life. Different types of wireless networks are being deployed for different purposes, depending primarily on their coverage capabilities (for example, wireless local area networks provide short coverage while cellular networks provide wide range network access) and there may be other factors such as cost and bandwidth. IP is playing a fundamental role in the convergence of heterogeneous wireless networks. However, to reap the full benefits associated with each of the underlying wireless networks being connected to each other, we need to design, implement, and deploy internetworking wireless solutions that can provide seamless connectivity and mobility in cost-effective and efficient ways. In this work, we presented and discussed

some of the solutions and architectures that can support efficient internetworking and integration of heterogeneous wireless-access systems. Current roaming techniques among different wireless networks are inadequate in supporting continuity of application sessions in heterogeneous mobile environments. Innovative designs, architectures, and protocols are needed in several areas (for example, mobility management, end-to-end QoS, multimodal devices) to achieve full internetworking among heterogeneous wireless access systems.

ACKNOWLEDGMENT

This work was supported by grants from Sun Microsystems (Palo Alto) (EDUD-7824-000145-US), Microsoft Corporation (Seattle), and Ixia Corporation (Calabasas). We thank the anonymous reviewers for their candid remarks and suggestions which helped to improve the quality and presentation of this chapter. We would also like to express our sincere gratitude to the editor-in-chief, Hossein Bidgoli, for his patience, encouragement, and kind support throughout the preparation of this chapter.

GLOSSARY

Access Point (AP): An access point is a station that transmits and receives data. It connects users within a network and acts as a connection point between a wireless LAN and a wired network.

Bluetooth: Bluetooth evolved from the need to replace wires in short-range communications (e.g., serial cable between computers and peripherals) with short-range wireless links.

Global System for Mobile (GSM) Communications: GSM is a digital mobile telephone system that uses a variation of Time Division Multiple Access (TDMA).

Handoff: The process by which a mobile terminal keeps its connection active when it migrates from the coverage of one network access point to another.

HiperLAN: A set of wireless LAN standards. There are two specifications, namely, HiperLAN/1 and HiperLAN/2 which can provide link rates of 20 Mbits/s and 54 Mbits/s respectively in the 5 GHz range.

Horizontal Handoff: Handoffs that occur between access points of the same network technology.

Hot Spot: A wireless LAN node that can provide connectivity to the Internet from some specific location.

Internet Protocol (IP): A connectionless protocol that enables data transfer between computers on the Internet.

Internetworking: A term that describes software and hardware technologies and devices that enable users and their computers to interact through different types of networking technologies.

Local Area Network (LAN): A group of computers and devices sharing a wired/wireless link within a small geographic area.

Mobile IP: An Internet Engineering Task Force (IETF) standard protocol designed to allow a mobile device to move across different networks while maintaining its permanent IP address.

Personal Area Network (PAN): A computer network used for communication among computer devices close to a person. (Usually such networks span over a distance of up to 10 meters).

Session Initiation Protocol: An Internet Engineering Task Force (IETF) standard protocol to initiate interactive user sessions that involve multimedia elements such as video, voice, chat, gaming, and virtual reality.

Vertical Handoff: A handoff that occurs between access points belonging to different networking technologies.

Wide Area Network: A network that spans large distances, usually connecting many other networks together.

Wireless: A term that describes communications in which electromagnetic waves carry the signal over the communication path.

INTRODUCTION

The hardware and software progress of the last ten years has provided the basic elements (wearable computers, several wireless network technologies, devices for sensing and remote control, etc.) for the realization of pervasive computing and communication systems (Cook and Das 2004). We can envisage a physical world with pervasive, sensor-rich, network-interconnected devices embedded in the environment (Estrin et al. 2002). In these systems the environment is saturated with computing and communication capabilities that interact among them, and with the users. In this environment, virtually everything (from key chains to computers) is connected to the network and can originate and respond to appropriate communications. The nature of ubiquitous devices makes wireless networks the easiest solution for their interconnection. Furthermore, in a pervasive computing environment, the infrastructure-based wireless communication model is often not adequate: it takes time to set up the infrastructure network, and the costs associated with installing infrastructure can be quite high. These costs and delays may not be acceptable for dynamic environments in which people and/or vehicles need to be temporarily interconnected in areas without a preexisting communication infrastructure (e.g., inter-vehicular and disaster networks), or where the infrastructure cost is not justified (e.g., in-building networks, specific residential communities networks, etc.). In these cases, ad hoc networks provide a more efficient solution (Conti 2004).

In the ad hoc networking paradigm, mobile devices self-organize to create a network by exploiting their wireless network interfaces, without the need for any pre-deployed infrastructure. The simplest ad hoc network is a peer-to-peer network formed by a set of stations within range of one another that dynamically configure themselves to set up a temporary single-hop ad hoc network. Bluetooth piconet is probably the most widespread example of a single-hop ad hoc network (Bisdikian 2001). 802.11 wireless local area networks (WLANs) can also be implemented according to this paradigm, thus enabling communications among laptops without the need for an

access point. Several emerging wireless network standards support the ad hoc networking paradigm, including IEEE 802.15.4 (also known as Zigbee) for short-range low data rate (< 250 kbps) networks, Bluetooth (IEEE 802.15.1) for personal area networks, and the 802.11 standards family for high-speed medium-range ad hoc networks (Conti 2004).

Single-hop ad hoc networks interconnect devices that are within the same transmission range. This limitation can be overcome by exploiting the multihop ad hoc paradigm. In a multihop network the network nodes (e.g., the users' mobile devices) must cooperatively provide the functionalities usually provided by the network infrastructure (e.g., routers, switches, servers). Nearby nodes can communicate directly by exploiting a single-hop wireless technology (e.g., Zigbee, Bluetooth, 802.11, etc.), whereas devices that are not directly connected communicate by forwarding their traffic via a sequence of intermediate devices (Chlamtac, Conti, and Liu 2003; Basagni et al. 2004). A multihop ad hoc network is often referred to as a *mobile ad hoc network* (MANET). MANET is not a new concept; in fact, it has been around for over twenty years, mainly used with tactical battlefield networks (Chlamtac, Conti, and Liu 2003). Recently, emerging wireless networking technologies for consumer electronics are pushing multihop networks outside the military domain. Pure multihop mobile ad hoc networks are attractive for specialized scenarios like disaster recovery, vehicle-to-vehicle communications, and home networking but currently have a very limited mass-market deployment. To turn mobile ad hoc networks in to a commodity, we should move to a more pragmatic scenario in which multihop ad hoc networks are used as a flexible and low-cost extension of the Internet. Indeed, a new class of networks is emerging from this view: the *mesh networks* (Bruno, Conti, and Gregori 2005). Unlike MANETs, in which every routing node is mobile, routing nodes in mesh networks are stationary and form the network's backbone, which has connections to the Internet. Client nodes connect to the mesh nodes and use the backbone to access the Internet. Mesh networks scenarios are moving mobile ad hoc networking

from disaster-relief and battlefield scenarios to the main networking market.

Whereas mesh networks represent a short-term direction for the evolution of MANETs, *opportunistic networking* constitutes a long-term direction for the evolution of the ad hoc networking concept by opportunistically exploiting, for data delivery, nodes' mobility and contacts with other nodes/networks. In opportunistic networks the communication is still multihop, with intermediate nodes acting as routers, but in this case forwarding is not "on the fly"; intermediate nodes store the messages when no forwarding opportunity exists (e.g., no other nodes are in transmission range, or neighbors are not suitable for that communication) and exploit any contact opportunity with other mobile devices to forward the data toward the destination. In this view, sender and receiver do not need to be connected at the same time to the network via a multihop path (as in traditional MANET) to communicate. Nodes can be temporarily disconnected and/or the networks can be partitioned. It is the nodes' mobility that creates communication opportunities (Fall 2003; Li and Rus 2000; Shah et al. 2003; Zhao, Ammar, and Zegura 2004). This networking paradigm is well suited to a world of pervasive devices equipped with various wireless networking technologies (802.11 family, Bluetooth, ZigBee, etc.) that are frequently out of range from a network but in the range of other networked devices, and sometime cross areas where some type of connectivity is available (e.g., WiFi hotspots).

Within the ad hoc networking field, wireless sensor networks have a special role. A sensor network is composed of a large number of small sensor nodes, which are typically densely (and possibly randomly) deployed inside the area in which a phenomenon is being monitored. Wireless multihop ad hoc networking techniques constitute the basis for sensor networks, too. However, the special constraints imposed by the unique characteristics of sensing devices, and by the application requirements, make the solutions designed for multihop ad hoc networks (generally) not suitable for sensor networks. Sensor networks utilize on-board batteries with limited energy that, in most application scenarios, cannot be replenished by direct human/machine intervention; therefore, power management is a pervasive issue in the overall design of a sensor network. In addition, sensor networks produce a shift in the networking paradigm: from node-centric to data-centric. The aim of a sensor network is to collect information about events occurring in the sensor field, rather than supporting the communications between nodes.

This chapter reviews the basic principles behind multihop ad hoc networks and sensor networks, and presents the most promising application scenarios.

MOBILE AD HOC NETWORKS

Mobile ad hoc networks are formed dynamically by a set of mobile nodes that are connected via wireless links without using any existing network infrastructure, such as a base station, for their operations (hence they are also referred to as infrastructure-less). The nodes are free to move randomly and organize themselves arbitrarily; thus,

the network's wireless topology may change rapidly and unpredictably. Such networks may operate in a stand-alone fashion, or they may be connected to the Internet. However, the ad hoc network flexibility and convenience come at a price. Indeed, in addition to the traditional problems of wireless networking, the multihop nature and the lack of fixed infrastructure add a number of characteristics, complexities, and design constraints that are specific to these networks (Chlamtac, Conti, and Liu 2003; Corson, Maker, and Cernicione 1999).

- *Autonomous and infrastructure-less.* A MANET does not depend on any established infrastructure or centralized administration.
- *Multihop routing.* Every node acts as a router and forwards other nodes' packets to enable information sharing between mobile hosts.
- *Dynamically changing network topologies.* Nodes' mobility causes frequent and unpredictable changes in the network topology, which may produce route changes, network partitions, and packet losses.
- *Variation in link and node capabilities.* Nodes might have different software/hardware resources and configurations, thus generating a heterogeneous network that is complex to manage. For example, nodes may be equipped with heterogeneous interfaces that result in asymmetric links.

To cope with these issues, several functions and protocols need to be implemented in a MANET protocol stack. This has produced extensive research activities in academia and industry. The Internet Engineering Task Force (IETF) MANET Working Group (WG) has the main role in standardizing protocols for mobile multihop ad hoc networks (IETF Mobile Ad Hoc Networks Working Group n.d.). The IETF MANET WG proposes a view of mobile ad hoc networks as an evolution of the Internet. This mainly implies an Internet protocol (IP)-centric view of the network, as well as the use of a layered architecture. This paradigm has greatly simplified network design and made easier the interconnection to the Internet. However, as explained later in this chapter, this approach limits the development of efficient solutions that are very important in a resource-constrained environment such as MANET. For this reason, new mobile ad hoc networks organizations based on the cross-layering approach are emerging.

MANET Architecture and Protocols

This section briefly reviews the main protocols (see Figure 1) required to support distributed applications in a mobile ad hoc environment. In the presentation we follow a layered approach, moving from the enabling technologies up to the applications.

Enabling Technologies

Enabling technologies are a fundamental building block of ad hoc networks by providing wireless interfaces able to guarantee direct single-hop communications between users' devices. Currently, connectivity is provided by

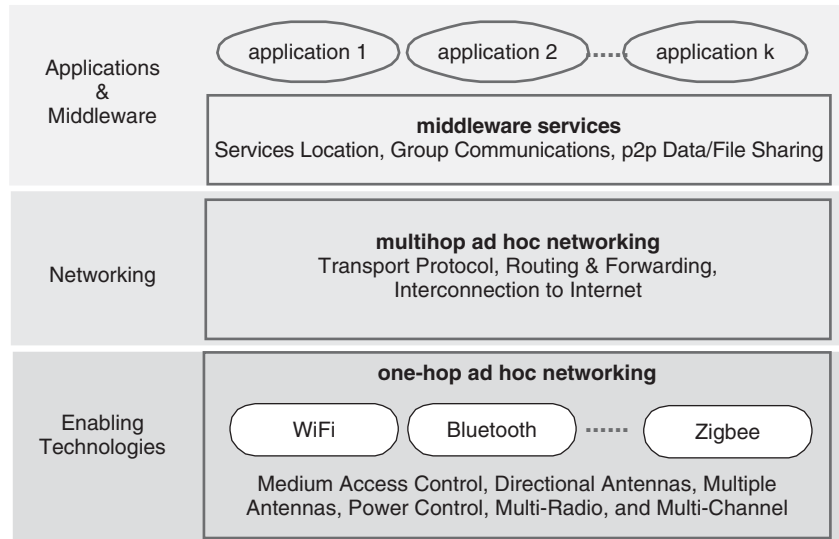

Figure 1: MANET layered architecture

wireless LANs (e.g., 802.11 WLAN standard) or somewhat smaller and less expensive Bluetooth devices. However, to provide the network connectivity to sensor nodes, technologies cheaper, simpler, lighter, and with lower power than these are necessary. These solutions should be able to support low bit rates (e.g., less than 100 Kbps), short ranges (few meters), low power requirements, and, above all, they must be extremely inexpensive. The IEEE 802.15.4 specification, also known as Zigbee, is one of the most promising solutions for short-range, low data rate (< 250 kbps), personal area networking. Specifically, 802.15.4 is designed to address wireless networking requirements for industrial control, home automation and control, inventory management, and wireless sensor networks (Callaway et al. 2002). A detailed discussion of enabling technologies for ad hoc wireless networks can be found in (Conti 2004).

The use of 802.11 technologies strongly constrains the size of multihop ad hoc networks. Indeed, both theoretical and experimental results indicate that with current technology only small-scale (i.e., 2–20 nodes) and moderate-scale (i.e., 20–100 nodes) ad hoc networks can be implemented in an efficient way. Specifically, in Gupta and Kumar (2000), it is shown that in an ad hoc network with n nodes the per-node throughput is bounded by c/\sqrt{n} , where c is a constant. In addition, experimental results (Gupta, Gray, and Kumar 2001) indicate that with current technologies the per-node throughput decays as $c'/n^{1.68}$, hence, only small- and moderate-scale ad hoc networks can be implemented in an efficient way. These results are confirmed by estimates reported in Gunningberg et al. (2005), which it has been pointed out that, with 802.11 technology, an ad hoc horizon exists—at two to three hops and 10 to 20 nodes—where MANET benefit virtually vanishes. The 802.11 performance limitations are strongly related to the carrier sense multiple access with collision avoidance (CSMA/CA) protocol used for controlling the access to the channel. Indeed, as pointed out in Anastasi et al. (2005), the CSMA/CA protocol induces complex

relationships between the network nodes. Specifically, it is important to be aware of the impact of the transmission and physical carrier sensing ranges on the network performance. The transmission range is the zone around the sender in which the packet reception probability is high and pretty stable. Beyond the transmission range, a gray zone exists in which the packet reception probability drops toward zero in a somewhat random way (depending on the antennas' characteristics). Finally, a pretty large zone exists in which the packet reception probability is zero, but carrier sensing is active (physical carrier sensing range). As shown in Anastasi et al. (2005), the aforementioned channel model applies also to other technologies that use the CSMA/CA medium access control protocol, for example, Motes sensor networks (Motes n.d.).

A novel and promising direction for reducing the interference among stations is based on the use of directional antennas (Ramanathan 2004). 802.11 ad hoc networks typically use omnidirectional antennas. With omnidirectional antennas, while two nodes are communicating using a given channel, the MAC protocol requires that all other nodes in the vicinity (physical carrier sensing range) stay silent. With directional antennas, two pairs of nodes located in each other's vicinity may potentially simultaneously access the channel, depending on the directions of their transmissions. Directional antennas can adaptively select radio signals of interest in specific directions while filtering out unwanted interference from other directions. This can increase spatial reuse of the wireless channel. In addition, the higher power gain of directional antennas (with respect to omnidirectional antennas) extends the node transmission range (Ramanathan 2001).

Enhancements in the physical layer technologies (e.g., multi-antenna platforms, the use of orthogonal frequency division multiplexing [OFDM] as a multiple-access paradigm, improved signal processing schemes, and software defined radio) are expected to be helpful in solving performance limitations of current wireless LAN technologies (Baccarelli et al. 2005).

Networking Protocols

The aim of the networking protocols is to use the one-hop transmission services provided by the enabling technologies to construct end-to-end (reliable) delivery services, from a sender to one (or more) receiver(s) outside its transmission range by exploiting the services offered by intermediate nodes. The efforts of researchers working on MANET mainly concentrated on solving these issues (Chlamtac, Conti, and Liu 2003).

The simplest solution is based on flooding the messages through the network. Of course, flooding does not scale, and hence this approach is only suitable for limited size networks. Controlling the flooding area and/or the number of messages to flood can help to refine the technique. For example, flooding can be used when the first message has to be sent from the sender to the receiver to discover the receiver location, then successive packets can be delivered along the path discovered during delivery of the first message. Identifying the path between the sender and the receiver, and then delivering the packets along this path, is exactly the objective of routing and forwarding algorithms, respectively. Numerous routing protocols and algorithms have been proposed, and their performance under various network environments and traffic conditions have been studied and compared. Several surveys and comparative analyses of MANET routing protocols have been published (e.g., Belding-Royer 2004).

A preliminary classification of the routing protocols can be done via the type of cast property, i.e. whether they use *unicast*, *geocast*, *multicast*, or *broadcast* forwarding (Chlamtac, Conti, and Liu 2003). Broadcast is the basic mode of operation over a wireless channel; each message transmitted on a wireless channel is generally received by all neighbors located within one hop from the sender. The simplest implementation of the broadcast operation to all network nodes is by flooding, but this may cause the *broadcast storm problem* as a result of redundant rebroadcast (Ni et al. 1999). Schemes have been proposed to alleviate this problem by reducing redundant broadcasting (see Stojmenovic and Wu 2004).

Unicast forwarding refers to one-to-one communication in other words, one source transmits data packets to a single destination. Multicast routing protocols come into play when a node needs to send the same message, or stream of data, to multiple destinations. Geocast forwarding is a special case of multicast that is used to deliver data packets to a group of nodes situated inside a specified geographical area. From an implementation standpoint, geocasting is a form of “restricted” broadcasting: messages are delivered to all of the nodes that are inside a given region.

The analysis of routing algorithms is beyond the scope of this chapter; we refer the interested reader to Basagni et al. (2004) and Chlamtac, Conti, and Liu (2003). Hereafter, we only briefly discuss unicast routing to discover a one-to-one communication path (i.e., one source transmits data packets to a single destination), because this is the basic service for building a multihop ad hoc network.

The primary goal of unicast routing protocols is the correct and efficient route establishment and maintenance between a pair of nodes, so that messages may

be delivered reliably and in a timely manner. This is the target of classical Internet link-state (e.g., open shortest path first [OSPF]) and distance-vector (e.g., routing information protocol [RIP]) routing protocols (Stevens 1994), but MANET characteristics make the direct use of these protocols infeasible. Internet protocols have been designed for networks with almost static topologies (therefore unable to keep pace with frequent link changes occurring in ad hoc environments), in which routing protocols run in specialized nodes with plentiful resources (i.e., energy, memory, processing capability, etc.). On the other hand, MANET routing protocols must operate in networks with highly dynamic topologies in which routing algorithms run on resource-constrained devices. MANET routing protocols are typically subdivided into two main categories: *proactive routing protocols* and *reactive (on-demand) routing protocols* (Belding-Royer 2004). Proactive routing protocols are derived from legacy Internet distance-vector and link-state protocols. They attempt to maintain consistent and updated routing information for every pair of network nodes by propagating, proactively, route updates at fixed time intervals. Reactive on-demand routing protocols, on the other hand, establish the route to a destination only when there is a demand for it. The source node in the route discovery process usually initiates the route request. Once a route has been established, it is maintained until either the destination becomes inaccessible or the route is no longer used (Belding-Royer 2004). Most work on routing protocols is taking place in the MANET Working Group, where four routing protocols are currently under standardization. These include two reactive routing protocols, ad hoc on-demand distance vector (AODV) and dynamic source routing (DSR), and two proactive routing protocols, optimized link state routing (OLSR) and topology broadcast based on reverse-path forwarding (TBRPF; IETF Manet Working Group n.d.). In addition to proactive and reactive protocols, another class of unicast routing protocols can be identified: *hybrid protocols*. The *zone-based hierarchical link state routing protocol* (ZRP; Samar, Pearlman, and Haas 2004) is a hybrid protocol that combines both proactive and reactive approaches, thus trying to bring together the advantages of the two approaches. ZRP defines around each node a *zone* that contains the neighbors within a given number of hops from the node. Proactive and reactive algorithms are used by the node to route packets within and outside the zone, respectively.

Location-aware routing protocols are a special case of routing protocols that use the nodes' position (i.e., geographical coordinates) for data forwarding. Specifically, a node selects the next hop for packets' forwarding by using the physical position of its one-hop neighbors and the destination node. The packets are forwarded to a neighbor in the receiver direction; for this reason, these routing protocols are also referred to as geographic routing protocols. Location-aware routing does not require routes' establishment and maintenance. No routing information is stored. The use of geo-location information avoids network-wide searches, because both control and data packets are sent toward the known geographical coordinates of the destination node. These features make location-aware routing protocols quickly adaptive to

route changes and more scalable than unicast protocols such as AODV, DSR, and OLSR.

A large number of location-aware routing algorithms have been proposed in the literature. A survey of location-aware routing algorithms can be found in Giordano, Stojmenovic, and Blazeovic (2003) and Widmer et al. (2003).

The low reliability of wireless communications coupled with nodes' mobility and multihop forwarding make packet loss a highly probable event in multihop ad hoc networks; hence, reliable transport protocols are often required to guarantee that the receiver sees exactly the same stream of bytes delivered by the sender. This is the task of the transmission control protocol (TCP; Stevens 1994), which indeed is the solution generally adopted for MANETs as well. Unfortunately, TCP was conceived for wired networks in which nodes do not change their position over time. Furthermore, it assumes that packet losses are almost always due to congestion phenomena causing buffer overflows at intermediate routers. These assumptions do not hold in MANETs. The MANET topology may change very frequently as a result of nodes' mobility. In addition, nodes may fail because of battery exhaustion (Chlamtac, Conti, and Liu 2003). Finally, congestion phenomena as intended in the Internet are rare events in MANETs, because packet losses due to link-layer contentions are largely predominant (Fu et al. 2003). To improve the performance of the TCP protocol in multihop ad hoc networks, several proposals have been presented (see, e.g., Wang and Zhang 2002; Liu and Singh 2001; Sundaresan et al. 2003). Almost all of these proposals are modified versions of the legacy TCP protocol used in the Internet. However, TCP-based solutions might not be the best approach when operating in MANET environments. Identifying a reliable and robust transport protocol for multihop ad hoc networks is still an open research issue. The interested reader is redirected to Chlamtac, Conti, and Liu (2003) and Anastasi et al. (2005), for an analysis of the TCP problems and new transport protocol proposals.

Middleware and Applications

Currently, in MANET the applications run directly on top of the transport layer by exploiting (via the legacy socket interface) the services offered by the TCP and UDP protocols. No middleware services are generally implemented, but each application has to implement all the services it needs. This constitutes a major complexity/inefficiency in the applications development, which can be fixed with the development of middleware platforms tuned on the unique MANET features. Currently, research on middleware for mobile ad hoc networks is still in its infancy and only recently did middleware proposals for mobile ad hoc environments appear (e.g., see Bellavista, Corradi, and Magistretti 2005, and references herein). Because ad hoc networks share many concepts with the peer-to-peer (p2p) computing system, exploiting the p2p paradigm for designing MANET middleware platforms is emerging as a very promising direction (Conti, Delmastro, and Turi 2006). In Borgia et al. (2005) and Conti, Gregori, and Turi (2005), the authors

investigate the efficiency of p2p middleware platforms when implemented on mobile ad hoc networks.

In spite of the massive research efforts, multihop ad hoc networks still have limited usage scenarios. More precisely, multihop ad hoc networks are generally used either for implementing tactical networks (e.g., military communications and automated battlefields) or for supporting communications in specialized civilian scenarios (e.g., disaster recovery, planetary exploration, vehicular networks, etc.). On the other hand, general-purpose civilian applications able to push a mass-market deployment of these networks have not yet been identified. A first step in this direction is reported in MobileMAN Project Deliverable D10 (n.d.), in which new application scenarios (city cabs, mobile games, and shopping malls) have been identified that can leverage the ad hoc technology to provide valuable services to the users. Specifically, the analysis of the city cab scenario (i.e., the use of 802.11 ad hoc networks to replace the currently used taxi radio dispatch systems) has shown that such a system is viable both economically and technically (Huang et al. 2005).

Cross-Layering Functions

The network functions presented in the previous section are implemented by protocols organized according to a layered architecture. However, in a mobile ad hoc network, a set of functionalities exists that may affect (almost) all layers and require interactions among different layers for their efficient implementation. These functionalities include, among others, energy management, security, and quality of service (Chlamtac, Conti, and Liu 2003).

Energy Management

In legacy wireless networks, the objective of power management policies (hereafter, we use energy and power management interchangeably) is to minimize the battery consumption of the users' devices (Anastasi, Conti, and Passarella 2005). This is achieved by maintaining the users' devices in a low battery consumption state (e.g., doze mode). These policies are not useful in a MANET. In multihop ad hoc networks, the devices spend a significant amount of their energy to act as routers contributing to routing and forwarding the network traffic. A selfish mobile device that remains most of the time in the doze mode, without contributing to routing and forwarding, maximizes its battery lifetime but jeopardizes the network. Therefore, in multihop ad hoc networks, the objective of power management policies is to maximize the network lifetime rather than minimize the mobile-device power consumption (Ephremides 2002). Two main techniques are used (often in conjunction) to achieve this objective: i) controlling the number of active nodes, and ii) controlling the nodes' transmission power (Feeney 2004). In the first case, the basic idea is that, when a region is dense in terms of mobile devices, only a small number of them need to be turned on in order to forward the traffic. To achieve this, a set of mobile devices is identified that must guarantee network connectivity (to participate in packet forwarding), and the remaining mobile devices can spend most of the time in doze mode to minimize

power consumption. Periodically, the set of active mobile devices is recomputed by selecting alternative paths in a way that maximizes the overall network lifetime.

Controlling the mobile-device transmission power is the other main direction for power management in ad hoc networks. Transmission power is highly correlated with power consumption. It determines both the amount of energy drained from the battery for each transmission and the number of feasible links. By increasing the transmission power we increase the per-packet transmission cost (negative effect), but we decrease the number of hops to reach the destination (positive effect) because more and longer links become available. Finding the balance is not simple. On one hand, we have to consider that the signal strength has an exponential decay; hence, from the transmission standpoint, to cover the sender-to-receiver distance a multihop path generally requires less power. On the other hand, on a multihop path the delay (due to the multiple hops) as well as the processing energy (to receive and locally process a packet) increase. Sterbenz et al. (2002) discuss the transmission-power impact on the network connectivity.

Security Issues in Ad Hoc Networks

The wireless, mobile, and self-organizing nature of ad hoc networks brings new security challenges to the network design. Mobile wireless networks are generally more vulnerable to information and physical security threats than fixed wired networks. Vulnerability of channels and nodes, absence of infrastructure, and dynamically changing topology make ad hoc network security a difficult task (Buttayan and Hubaux 2002). Broadcast wireless channels allow message eavesdropping and injection (vulnerability of channels). Nodes do not reside in physically protected places and therefore can easily fall under the attackers' control (node vulnerability). The absence of infrastructure makes the classical security solutions based on certification authorities and online servers inapplicable. The security of routing protocols in the MANET dynamic environment is an additional challenge. Security mechanisms that solely enforce the correctness or integrity of network operations also would not be sufficient in ad hoc networks. A basic requirement for keeping the network operational is to enforce ad hoc nodes' contribution to network operations, despite the conflicting tendency (motivated by the energy scarcity) of each node toward selfishness. Therefore, mechanisms for cooperation enforcement constitute a relevant part of ad hoc network research on security (Conti, Gregori, and Maselli 2004).

Quality of Service

A network's ability to provide quality of service (QoS) depends on the intrinsic characteristics of all the network components, from transmission links to the media access control (MAC) and network layers. MANET characteristics indicate that this type of network may provide weak support to QoS. Wireless links have a (relatively) low and highly variable capacity, as well as high loss rates. Topologies are highly dynamic and have frequent link breakages. Random access MAC protocols, which

are commonly used in this environment (e.g., 802.11b), have no QoS support. Furthermore, MANET link layers typically run in unlicensed spectrums, making it more difficult to provide QoS guarantees (Macker and Corson 2004). This scenario indicates not only that QoS guarantees will be difficult to achieve in a MANET but that if nodes are *highly mobile*, even statistical QoS guarantees may be impossible to attain. Providing QoS in mobile ad hoc networks is a very complex and challenging problem (Macker and Corson 2004), and this generates a great deal of research activities at different layers of the protocol stack, including QoS MAC, QoS routing, and resource-reservation signaling (Chlamtac, Conti, and Liu 2003).

Cross-Layering in Mobile Ad Hoc Networks Design

An efficient implementation of the cross-layer functions can be achieved by avoiding a strict layering approach in which the protocols at each layer are developed in isolation, and instead taking advantage of the interdependencies among different layers. For example, from the energy management standpoint, power control and multiple antennas at the link layer are coupled with scheduling at the MAC layer, and with energy-constrained and delay-constrained routing at the network layer.

To effectively exploit interdependencies among different layers, researchers have investigated new organizations of the MANET protocol stack based on *cross-layering* (Conti et al. 2004). The basic idea behind cross-layering is to make information produced/collected by a protocol available to the whole protocol stack, so as to enable optimizations and improve network performance. Indeed, the studies on cross-layering pointed out that functionalities usually pertaining to a single layer also can improve their performance via cross-layer interactions with other network functionalities. For example, the performance of routing and forwarding protocols can significantly improve by exploiting the information available in the MAC and physical layer. However, some researchers (Kawadia and Kumar 2005) have pointed out that the layer separation principle, by guaranteeing a modular design of the protocol stack, is a value to be maintained. An "unbridled" cross-layer design can produce a spaghetti-like code that is impossible to maintain in an efficient way, because every modification needs to be propagated to all protocols.

Relaxing the Internet layered architecture by enabling cross-layer interactions among protocols but still maintaining a layered organization and the layer separation principle, represents a good compromise between the two positions (layering and cross-layering). This is made possible by introducing a vertical module, called *network status* (NeSt), which controls all cross-layer interactions through data sharing (see Conti et al. (2004) and Mobile-MAN Project Deliverable D13 (n.d.) for details). Specifically, the NeSt supports vertical communications among the layers by acting as a repository for information collected by network protocols (see Figure 2). Each protocol can access the network status to share its data with other protocols and interact with them. By standardizing the NeSt interface (which defines how protocols can

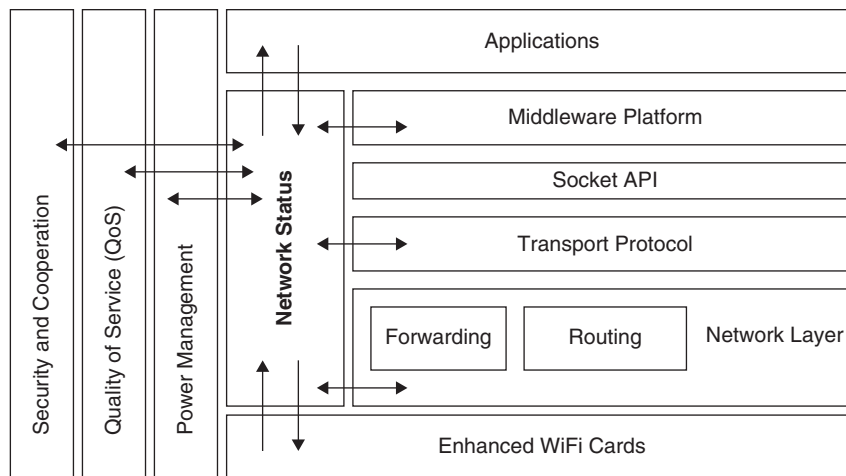

Figure 2: NeSt architecture

access/modify shared data), the layer separation principle is preserved. Indeed, in this way, cross-layer interactions do not directly take place between the interested protocols but are implemented using the abstractions exported by the NeSt, without modifying the interfaces between adjacent layers. Protocols have to implement the NeSt interface to exploit cross-layer optimizations, but no constraint exists on protocols, internal implementation. As long as the NeSt interface is implemented, a protocol can be replaced with a new release (or even with a brand-new protocol) without affecting the other protocols of the stack. In addition, using legacy protocols (i.e., no network-status enabled) is still possible although with degraded performance (i.e., without cross-layer optimizations). For example, using the legacy TCP protocol implies that cross-layer optimizations will not occur at this layer and that the transport protocol will not provide any information to the network status component. However, the overall protocol stack still operates correctly.

The design of a NeSt module from both a functional and an implementation standpoint is discussed in (Conti, Maselli, and Turi 2006). The effectiveness of the NeSt-based approach has been extensively evaluated by simulation in Conti, Gregori, and Turi (2005) and Conti, Gregori, and Maselli (2005) whereas Borgia et al. (2005) and Borgia, Conti, and Delmastro (2006) present experimental results obtained by implementing the NeSt in a multihop ad hoc network prototype.

FROM MANET TO MESH NETWORKS

As discussed earlier, currently mobile multihop ad hoc networks are tailored to very specialized missions (e.g., large-scale military applications with thousands of ad hoc nodes) or specialized civilian applications (e.g., disaster recovery, planetary exploration, etc.), and they have a very limited impact on the wireless market. By relaxing one of the main constraints of mobile ad hoc networks (the network is made of user devices only and no infrastructure exists), we move to a scenario in which multihop ad hoc networks are not isolated but emerge as a flexible and low-cost extension of the Internet. Indeed, a

new class of networks is emerging from this view: the *mesh networks* (Bruno, Conti, and Gregori 2005). Mesh networks are built upon a combination of fixed and mobile nodes interconnected via wireless links to form a multihop ad hoc network (Bruno, Conti, and Gregori 2005). Different from *pure* multihop ad hoc networks, a mesh network introduces a *hierarchy* in the network architecture by introducing dedicated nodes (called *mesh routers*) communicating wirelessly to construct a *wireless backbone*. The wireless backbone has a (limited) number of connections with the wired Internet. Mobile/nomadic users obtain a multihop connectivity to the Internet by connecting to the closest mesh router (Akyildiz, Wang, and Wang 2005; Bruno, Conti, and Gregori 2005). Figure 3 illustrates the mesh network architecture, highlighting the different components and the system layers.

It is worth noting that, even though mesh networks require the existence of a wireless infrastructure (wireless mesh routers), the cost of this infrastructure is significantly lower than the cost of a traditional wired infrastructure. Indeed, broadband wired access to the Internet (e.g., via T1 or T3 access lines) is very expensive. In a mesh network, we need to provide only a limited number of *wired* ingress/egress points toward the Internet, whereas the mesh routers are in charge of routing the traffic through the wireless backbone toward these access points.

Even though mesh networks are a recent technology, they have already shown potential in the wireless market. Indeed, interesting wireless-mesh-network civilian applications have been recently deployed (Bruno, Conti, and Gregori 2005), for example:

- *Intelligent transportation systems.* The Portsmouth Real-Time Travel Information System (PORTAL) is an effective example of a mesh-network system aimed at providing real-time travel information to bus passengers in the city of Portsmouth (e.g., where the bus is and its scheduled arrival time).
- *Public safety.* The San Mateo Police Department in the Bay Area exploited a mesh network for broadband communications among all its vehicles (patrol cars, motorbikes, and bicycles).

Figure 3: A wireless mesh network

- *Public Internet access.* The wireless mesh networks are the ideal solution to provide both indoor and outdoor broadband wireless connectivity in urban, suburban, and rural environments; see, for example, the metro-scale broadband city network in the City of Cerritos, California.
- *Community networks.* These networks, usually built using off-the-shelf technology (mainly 802.11), provide Internet access to a community of users that can share the same Internet access link. Several examples of this are: Seattle Wireless, Champaign-Urbana Community Wireless Network (CUWiN), the San Francisco BAWUG, and the Roofnet system at MIT.

FROM MANET TO OPPORTUNISTIC NETWORKING

MANET applications and services rely on the end-to-end principle (i.e., a path must continuously exist between the sender and a receiver for successful communications). In reality, end-to-end connectivity is a strong requirement only for interactive services such as voice over IP (VoIP), gaming, and video streaming; many other applications can still correctly operate relaxing the end-to-end constraint. For example, data applications like messaging, e-mails, data sharing, and so forth can tolerate sender-receiver disconnections. In principle, they can operate even if a sender-receiver path never exists (Fall 2003). This is a key point to overcome some of the main limitations of mobile multihop ad hoc networks in which network partitioning

causes the failure of ongoing communications, and/or nodes that are temporarily disconnected from the network cannot communicate. Indeed, in opportunistic networks, a node stores the messages in its local memory until a forwarding opportunity does not exist. In this way, packets are not discarded during network disconnections but are locally stored. Specifically, in opportunistic networks the communication is still multihop with intermediate nodes acting as routers that forward the messages addressed to other nodes; however, in this case, forwarding is not “on the fly” because intermediate nodes store the messages when no forwarding opportunity exists (e.g., no other nodes are in the transmission range, or neighboring nodes are not considered useful for that communication) and exploit any contact opportunity with other mobile devices to forward information. For example, as shown in Figure 4, the man at the desktop opportunistically transfers, via a WiFi link, a message for his wife to a car crossing its area, hoping that the car will carry the information closer to its destination. Following the same approach, the car uses its Bluetooth radio to forward the message to the mobile phone of a woman who is going to the airport to catch a plane to a city close to the receiver’s expected location. Proceeding the same way, the message arrives at the receiver. As is clearly shown in this example, a network connection between the man and his wife never exists, but, by opportunistically exploiting the contacts among heterogeneous devices, a message is delivered hop by hop (hopefully) closer to the destination and eventually is delivered to the receiver.

Figure 4: Opportunistic networking

Opportunistic networking is the evolution of the ad hoc networking concepts to opportunistically exploit users' mobility, which is "hostile" for legacy multihop ad hoc networks. Indeed, whereas mobility is one of the main MANET problems because it causes (due to node movement) route breakages, network disconnections, and partitions, in opportunistic networks nodes' mobility creates opportunities for communicating. The network can be partitioned and/or the receiver disconnected by the network. The mobility of nodes creates the communication opportunities. This behavior is well suited for a world of pervasive devices equipped with various wireless networking technologies (802.11 family, Bluetooth, ZigBee, etc.) that are frequently out of range of a network but are in range of other devices and sometimes cross areas in which some type of Internet connectivity is available (e.g., WiFi hotspots).

The concept of opportunistic networking can be further extended to mean that we exploit opportunistically any available communication technology (e.g., cellular, WiFi, Internet, etc.). In current pervasive systems in which nodes often have multiple network interfaces, at any time the communication paradigm would opportunistically choose for data forwarding the interface that is considered the most suitable for the given context (Haggle n.d.).

The Internet Research Task Force (IRTF) *Delay-tolerant networking* (DTN) Research Group is working to standardize architecture and protocols for enabling communications in networks with intermittent connectivity in which continuous end-to-end connectivity cannot be assumed (DTN n.d.). The basic idea is to construct an overlay, a *bundle layer*, on top of existing networks. The bundle layer exploits storing and forwarding of the information to support asynchronous data transfer between nodes in *challenged networks* with extreme communication delays and intermittent connectivity, such as interplanetary networks, military/tactical networks, disaster/emergency networks, underwater networks, and some forms of ad hoc sensor/actuator networks.

SENSOR NETWORKS

Sensor nodes constitute basic elements of pervasive environments. Recent advances in computing technology have led to the production of a new class of wireless, battery-powered, smart sensor nodes. These nodes are active devices with computing and communication capabilities that not only sample real-world phenomena

Figure 5: A simplified sensor node

but can also filter, share, combine, and operate on the data they sense (Raghunathan et al. 2002).

Figure 5 presents a simplified scheme of a sensor node. The basic units of a sensor node are: the sensing unit (made up of a set of sensors, e.g., acoustic, magnetic, temperature, light, sound, etc.), the processing unit, a network interface (typically a radio), and the energy-supply unit (typically, a limited energy battery; Anastasi, Conti, and Passarella 2005). In addition, depending on the type of application it may have other components as well (e.g., an actuator).

Different kinds of infrastructures can be deployed to deliver the information from the sensing field to the collecting place (sink). The advances in simple, low-power, and efficient wireless communication equipment made wireless sensor networks the most interesting way to deliver the sensed data to the mobile device(s) to collect/elaborate them. The simplest way is to use single-hop wireless communications: the sensor nodes directly communicate the sensed data to a data-collection center, often referred to as a sink (see Figure 6.a).

This communication model can be efficiently applied only when the distance between the sensor nodes and the sink is limited (30 meters). In other cases, the sensor-node technology constraints (limited transmission range of wireless communication interface and/or the excessive energy drained by the wireless interface for long-distance communications) and the characteristics of the environment in which the sensor network is deployed (e.g., natural barriers) make direct communications not feasible or

Figure 6: (a) Single-hop communications;
(b) Multihops communications

effective. Therefore, as shown in Figure 6.b, each sensor node delivers the collected data to one (or more) neighbor node, one hop away. By following a multihop communication paradigm, the data are routed to the sink and through this to the user. Therefore, multihop ad hoc techniques also constitute the basis for wireless sensor networks. However, the resource constraints of the sensor nodes and the application-oriented characteristics of sensor networks make solutions designed for multihop wireless networks generally not suitable for sensor networks (Akyildiz et al. 2002). First of all, sensor nodes are limited in power, computational capacity, and memory. Sensor networks utilize on-board batteries with limited energy that cannot be replenished in most application scenarios (Starner 2003). This strongly affects the lifetime of a sensor network and makes power awareness a critical factor in the design of sensor network protocols. One possibility in these cases is *energy harvesting* from the environment; for example, energy can be obtained from light sources via solar cells. Unfortunately, at this time, energy harvesting is still in the early stages, and current technologies make available only small amounts of energy. The interested reader can find a review of energy harvesting technology in *IEEE Pervasive Computing* (2005). Sensor nodes are prone to failure and therefore are densely deployed for reliability; the number of sensor nodes in a sensor network can be several orders of magnitude higher than the nodes in an ad hoc network; although the large number of devices provides natural redundancy, correlated failures as a result of software errors could be catastrophic. Sensor nodes, once deployed, will be unattended. This makes robust operation a priority.

Sensor networks also produce a shift in the networking paradigm, from node-centric to data-centric. The aim of a sensor network is to collect information about events occurring in the sensor field rather than supporting the communications between nodes. Sensor networks are deployed to achieve a specific objective via a collaborative effort of numerous sensor nodes; the architecture, protocols, and type of sensor nodes drastically change by modifying the application scenario. Each sensor network will have a different purpose and will be customized to fit the task in an optimized way. This may imply the use of customized hardware platforms as well as applications-specific software and protocols. Therefore, before further

discussing sensor networks organization, we survey possible application scenarios.

Sensor Network Applications

Sensor networks can be successfully applied in scientific research (habitat/environment monitoring), military scenarios (e.g., battlefield surveillance; reconnaissance of opposing forces; tracking of troops and equipment; nuclear, biological, and chemical attack detection, etc.), health applications (e.g., integrated patient monitoring), and commercial applications (e.g., monitoring material fatigue, structural control, managing inventory, factory process control and automation, vehicle tracking and detection, precision agriculture, etc.); see Akyildiz et al. (2002) and *IEEE Internet Computing* (2006).

Habitat and environmental monitoring include a large number of applications in which the use of sensor networks provides a very effective solution. Indeed, making regular observations of the environment is a complex and expensive task. In addition, human presence may have an impact on the monitoring of plants and animals in field conditions. For example, frequent visits can be a source of habitat modification that might bias environmental measurements. In addition, twenty-four-hour monitoring is not feasible for human beings. In this context, sensor networks represent a significant advance over traditional invasive methods of monitoring. Sensors can be deployed prior to sensitive period (e.g., breeding season, in the case of animals) or while plants are dormant or the ground is frozen (in the case of botanical studies). Several examples exist in the scientific literature of sensor network use for environment monitoring. These studies differ in the context and object to monitor; hence, different sensor networks have been adopted.

- The *Great Duck Island Habitat Monitoring* project (<http://www.greatduckisland.net>). This was a pilot application for monitoring migratory seabirds (Leach's Storm Petrel) on Great Duck Island, Maine. The project started in 2002 with thirty-two wireless sensor nodes to monitor the microclimates in and around nesting burrows. At the end of the field season in November 2002, over 1 million readings had been logged from the thirty-two

motes deployed on the island and made available on the Internet. A second-generation network was deployed in 2003 with about 150 nodes that formed a multihop network, transferring their data to a base station. Eventually, data were transferred via satellite to the database at the University of California at Berkeley.

- *Study of Hawaii rare and endangered species of plants* (Biagioni and Bridges 2002). The PODS project (<http://www.pods.hawaii.edu>) developed a sensor network to study the biology of typical rare plant species and the habitats they occupy in *Hawaii Volcanoes National Park*. The aim of the study was to collect measurements of the temperature, humidity, rainfall, wind, and solar radiation in the rare species' habitat. In addition, to make inferences about factors determining the species' distribution, measurements had to be taken in nearby areas that did not have the species under study. Sensor nodes (a computer with environmental sensors and, in some cases, a high-resolution digital camera) collected data and, by exploiting a multihop paradigm, moved data toward an Internet access node.

The use of sensor networks for habitat monitoring is a very active research area. Let us also remember the use of sensor nodes proposed by Intel and the University of California at Berkeley to create a *macroscope* (sensor nodes strapped at different elevations of a redwood tree) to study the microclimate around redwoods (Tolle et al. 2005), and the habitat-sensing activities carried out by the Center for Embedded Networked Sensing (CENS) at the University of California at Los Angeles.

The next challenge is to expand monitoring to more hostile environments such as glaciers. This is indeed the objective of the *Envisense GlacsWeb project*, which focuses on monitoring the glacial environment to study subglacial bed deformations (Martinez, Hart, and Ong 2004). The system is based on probes inserted fifty to eighty meters into the glacier. The probes collect measurement samples via pressure, temperature, and orientation sensors, and deliver them to a base station located on the glacier surface, from which they are delivered to the sink. Probes use a direct wireless link to communicate with the base station.

Sensor networks for environment monitoring are also the basis for many useful civilian applications such as forest fire detection, flood detection, and precision agriculture (e.g., to monitor microclimates throughout a vineyard and add water and fertilizer when needed). Randomly and densely deployed sensor nodes are extremely useful for the early detection and localization of fires in the forest. Alarms, propagated multihop through the sensor network, enable a quick reaction before the fire becomes uncontrollable. Similarly, sensor nodes that monitor water levels and rainfall can provide early warnings of possible flooding conditions, thus helping to reduce damages. Sensor networks are ideal for studying the effects of microclimate on plant growth, thus allowing scientists to better understand the ways in which to optimize yield and quality (precision agriculture).

Health monitoring is a very promising area for the application of wireless sensor networks. In this case, sensor networks are part of a wearable system used for health

monitoring. Physiological sensors (e.g., electrocardiogram, blood pressure, temperature) can be used to automatically collect physiological parameters to be delivered, via a body area network, to wearable devices for real-time processing and/or storing for future use (long-term observation). For example, the CodeBlue system (n.d.) developed at Harvard University exploits a wireless sensor network to raise an alert condition when vital signs fall outside of normal parameter values. The system, built on Mica2, MicaZ, and Telos platforms (Mica n.d.; Telos n.d.), monitors heart rate, oxygen saturation, and electrocardiogram data, and relays the data over a short-range wireless network to a set of devices, including personal digital assistants (PDAs), laptops, and ambulance-based terminals.

Tracking applications constitute another important field for sensor network applications. Instead of sensing environmental data, in this case sensor nodes are deployed to sense the presence of persons and objects. Objects can be tracked by simply tagging them with a small sensor node. The sensor node will be tracked as it moves through a field of sensor nodes that are deployed throughout the environment at known locations. The sensor nodes can be used as active tags that announce the presence of a device. Using this system, it becomes possible to ask where an object is. Tracking applications have an important role in the military field for monitoring friendly forces, equipment, and ammunition; every troop, vehicle, and piece of critical equipment can be tracked by attaching to it a sensor node that reports its status. A similar approach can be used, for example, to track and monitor doctors and patients inside a hospital.

Localization applications are among the most challenging applications that can be performed by a sensor network. For example, detecting and locating snipers is a challenging goal for armed forces and law enforcement agencies. Most successful sniper-detecting systems are based on exploiting a wireless sensor network that takes measurements of the acoustic events generated by a shot: the spherical wave (traveling at the speed of sound) produced by the muzzle blast and the shock wave generated by the supersonic projectile. By exploiting the measurements of acoustic events taken by the sensor network nodes, it is possible to determine the shooter's location and the bullet's trajectory (see, e.g., Maroti et al. 2004).

The examples above represent a set of the most promising scenarios for the utilization of sensor networks. However, sensor networks will likely be a pervasive technology that covers all aspects of life, including the arts (Burke et al. 2006).

Sensor Network Organization

The aim of a sensor network is to collect information about events that occur in the sensor field. To this end, a wireless sensor network is often organized as shown in Figure 7. Sensor nodes are densely deployed in the monitoring area, and the information collected by a sensor node is delivered to the sink by exploiting the multihop paradigm. Generally, in monitoring applications, knowledge of sensor locations is required to correctly report, for example, the origin of events generating an alarm.

Figure 7: A wireless sensor network

Location discovery has therefore received considerable attention from the sensor network research community. Savvides and Srivastava (2004) presents an excellent review of techniques and systems for location discovery in ad hoc and sensor networks.

In monitoring applications, several sensor nodes often collect the same (or highly correlated) information (e.g., in Figure 7, all sensor nodes close to the fire sense very high temperature values); hence, not all samples need to be delivered to the sink, but only a subset or some aggregated form (e.g., in Figure 7 it is enough to report to the sink the event “temperature higher than 100°C”). This means that, because of the redundancy of the sensed information, the delivery to the sink of the information collected by a given node can tolerate some losses in many applications. The data-centric nature of sensor network applications produces a shift in the networking paradigm with respect to the node-centric view used in legacy wired and wireless networks. In sensor networks, the correct detection of an event (possibly minimizing the energy) is the aim of the networking protocol, whereas correct delivery to the sink of all information generated by the sensor nodes is not only useless but also often undesirable because of the excessive energy costs and the increase in network congestion. Moreover, while in node-centric networks, the information is not manipulated inside the network (at most, packets can be discarded if resources are not available for forwarding them). In sensor networks, intermediate devices—traveling along the path from the sender (a sensor device) to the receiver (the sink)—can exploit the correlation in the observed data to reduce (via aggregation) the amount of information flowing into the network. For instance, in the Figure 7 example, a node does not forward all of the fire alarms it receives from downstream nodes but just a minimum number to guarantee that the event notification arrives at the sink. In general, each sensor node (to increase the energy efficiency of the system) aggregates the samples received by downstream nodes (e.g., combines the sampled values into a sum) before forwarding data to the sink. Indeed, in sensor networks, from the power consumption standpoint,

processing is a much cheaper operation than transmitting (Doherty et al. 2001; Starner 2003). In addition, *in-network processing* contributes to a better utilization of sensor-node limited bandwidth. Therefore, whereas in mobile ad hoc networks only protocols operating at layers 1–3 of the open systems interconnection (OSI) reference model participate in the operations inside the network (higher layers are affected only in the sender and receiver devices), in a sensor network higher layers (e.g., the presentation and the application layers in which compression and aggregation of data are applied to reduce redundancy in delivered data) also contribute to power-efficient data delivery, making the sensor network protocol stack cross-layer in nature (Conti et al. 2004). TinyDB (Madden et al. 2003) represents the extreme case, in which almost all of the networking functions are implemented in the application layer. A complete analysis of research issues for designing sensor network protocols can be found in Akyildiz et al. (2002).

Sensor Networks and Data Mules

So far we have assumed that sink(s) are fixed and that measurements taken from sensor nodes far from the sink are delivered to the sink via a complex multihop process. In many applications, collecting data from the sensor nodes can be implemented in a more efficient way by adding a further level to the system hierarchy. This additional level can be implemented by introducing mobile nodes inside the network (e.g., robots) that move inside the sensors field collecting the information from neighbor nodes via single-hop ad hoc wireless communications and then move close to the sink to deliver the collected data. These nodes are often referred to in the literature as *data mules* (Shah et al. 2003; Jea, Somasundara, and Srivastava 2005). Unmanned helicopters flying over the sensor field to collect data are an example of data mules (Henkel et al. 2006).

A mule-based sensor network is useful in sparse networks in which nodes are far from one another, thus making a multihop path too expensive from the energy

standpoint. In addition, this approach increases the nodes, battery lifetime, because sensor nodes are not involved in data forwarding.

The use of data mules may introduce significant energy savings in the sensor nodes because they have only to transmit their own data to the mobile nodes via short-range transmissions; on the other hand, data mules may increase the network cost, because complex mobile nodes need to be introduced and managed. One possible way to avoid this complexity is to opportunistically exploit as data mules any element that, for any reason, crosses the sensor field. For example, imagine sensor nodes spread out in an urban environment to take pollution measurements. To deliver sensor samples to a sink, we can opportunistically exploit city buses that come close to sensor nodes while moving along the streets. Via single-hop ad hoc communications, the buses collect data from the sensor nodes. The data are then delivered to the sink when the bus arrives inside the sink transmission range, or they are forwarded to other buses that have a better chance of arriving close to the sink. The effectiveness of this approach for collecting sensor data samplings in urban environments is investigated in Anastasi et al. (2006). Specifically, by exploiting simple sensor nodes (Berkeley motes), the authors show that in high-mobility scenarios as will (corresponding to vehicles moving along the city streets), the mules (vehicles) are able to collect reasonable amount of data from mote sensor nodes (Anastasi et al. 2006). A limitation of this approach is the extra delay in delivering data from the nodes to the sink, which makes this solution suitable mainly for delay-tolerant applications.

Sensor Networks and Actuators

In the previous section we introduced robots that move in the sensor fields to collect data from the sensor nodes and deliver them to the sink. In that case, the robots only collected data from the sensors; their actions did not depend on the information they collected. In a more general framework, the robots can also perform actions on the sensor field depending on the events detected by the sensors. For example, we can imagine a robot with water-sprinkling capabilities that receives fire alarms from sensor nodes and immediately operates to extinguish fire. This class of nodes, which operates on the sensor field to react to events detected by sensor nodes, is referred to in the literature as actuators or actors (Akyildiz and Kasimoglu 2004). The actors can be fixed and simple entities such as in-room water sprinklers, or resource-rich mobile robots equipped with significant processing and communication capabilities and high-capacity batteries, such as un-manned helicopters and battlefield robots. The design of sensor and actor networks presents several challenging research issues (Akyildiz and Kasimoglu 2004). Indeed, in this case we need to coordinate the sensor nodes with the actors, and coordinate the actors among themselves to select the actor(s) in charge of reacting to sensor-node detected events.

Underwater Sensor Networks

Monitoring the aquatic environment is emerging as a very interesting and challenging scenario for the use of

wireless sensor networks. This scenario includes, among others (Akyildiz, Pompili, and Melodia 2005):

- Oceanographic data collection for scientific exploration, pollution control, climate monitoring, weather forecasting, and so forth
- Disaster prevention, for example, by providing tsunami warnings to exposed areas
- Undersea exploration to detect valuable minerals or help in laying cables
- Tactical surveillance by detecting underwater vehicles (e.g., submarines) (Cayirici et al. 2006)

Underwater sensor networks add to the features of legacy sensor networks (a large number of nodes, energy limitations, etc.) unique characteristics of the underwater environment that make solutions for terrestrial sensor networks not directly applicable. Novel aspects of these networks are: i) acoustic communications, ii) three-dimensional (3-D) form, and iii) high node mobility.

Acoustic Communications

Due to poor performance of radio waves in aquatic environments, underwater communications exploit acoustic wireless communications (Proakis et al. 2001). The use of acoustic signals has a major impact on the design of underwater sensor networks. First of all, the propagation speed of acoustic signals in water (0.67 s/km) is five orders lower than the radio propagation speed. Furthermore, underwater acoustic communications are negatively affected by phenomena such as noise, multipath, path loss, and Doppler spread that cause high error rates and limit the available bandwidth to few kbits/sec (Akyildiz, Pompili, and Melodia 2005).

3D Dimension

Whereas terrestrial sensor networks often have a two-dimensional design (some 3D sensor networks are used in terrestrial networks for environmental monitoring; see the section entitled "Sensor Network Applications"), underwater sensor networks are generally deployed in a 3D space.

Node Mobility

Underwater sensor nodes, unless connected to surface buoys, are subject to water current, which in a typical condition moves the objects at a speed of 3–6 km per hour. This makes the network topology very unstable and impacts message routing and forwarding.

These issues open research challenges at all layers of the protocols' stack (Cui et al. 2006). An in-depth analysis of research issues and directions for tackling them are presented in Akyildiz, Pompili, and Melodia (2005).

CONCLUSION

The number of microprocessors residing in everyday electronics is continuously increasing, and this presents new advanced forms of interaction between humans, and between humans and the physical world. Wireless

networks are the natural tools for these interactions because they offer mobility and avoid wiring problems. Among these networks, ad hoc networking is rapidly gaining momentum because of its flexibility and low costs. The heterogeneity of devices to be interconnected (from small sensors and actuators to multimedia PDAs) and the large spectrum of communication requirements (from a few meters of coverage and a few kilobits of bandwidth to city-wide coverage and broadband communications) produced a set of ad hoc network technologies. At one extreme, we have sensor networks for communication among small-size, low-cost, and low-energy consumption devices (sensors) for which a high data rate is not necessary. At the other end of the spectrum we have mesh networks that, by exploiting an infrastructure of wireless mesh routers, guarantee the exchange of multimedia information among devices located in an urban area. This chapter has presented an updated overview of ad hoc networks by presenting their principles and by applications, and by pointing out the open research issues. Specifically, we discussed the relationships among different ad hoc networks and their application scenarios. The chapter began with an overview of MANET protocols and a discussion of the impact of cross-layering design on MANET architecture. Specifically, we presented an architecture that guarantees cross-layer interactions among protocols while maintaining a layered organization. Next, we discussed MANET evolution toward mesh and opportunistic networks. Mesh networks represent a short-term, market-driven evolution of MANETs. In these networks, routing nodes (mesh routers) are stationary and form a wireless ad hoc backbone, which has connections to the Internet. Client nodes use the backbone to access the Internet. On the other hand, opportunistic networking represents a long-term direction for the MANET evolution. In these networks, communications are single hop, and messages are forwarded from a node to one, or more, of its neighbors. Forwarding is performed when there is a significant probability that a node will move close to the destination or will be able to forward the data to nodes closer to the destination than itself. The last part of the chapter discussed ad hoc networking in the context of sensor networks. A sensor network is composed by a (possibly large) number of small sensor nodes, which are deployed inside an area to monitor. We extensively discussed the constraints on the network organization as a result of the limited resources of sensing devices and application requirements. Based on the application scenario, we presented different models for organizing a sensor network, including a brief overview of underwater sensor networks.

ACKNOWLEDGMENT

This work was partially funded by the Information Society Technologies program of the European Commission under the MobileMAN (IST-2001-38113) and HAGGLE (027918) grants. I wish to express my thanks to the anonymous referees for helpful comments and suggestions.

GLOSSARY

- Acoustic Wireless Networks:** Wireless networks that use acoustic signals for communication among nodes. Typically used in underwater environments.
- Actuator:** Robot able to perform actions on the sensor field as a reaction to the events detected by the sensor nodes.
- Ad Hoc Network:** Wireless network in which mobile devices communicate directly without relying on any pre-deployed infrastructure. This type of network is also referred to as an infrastructure-less network.
- Body Area Network (BAN):** Short-range (wireless) network for interconnecting devices distributed on the human body.
- Cross Layering:** A design principle for organizing the protocol stack exploiting interlayer dependencies. Through cross-layering a protocol can use the information collected at other layers of the protocol stack.
- Data Mule:** A mobile element that crosses a sensor field, collects data from sensor nodes, and delivers data to a sink.
- Delay-Tolerant Network (DTN):** Architecture and protocols standardized by the IRTF *Delay-tolerant networking* (DTN) Research Group for enabling communications in networks with intermittent connectivity in which continuous end-to-end connectivity cannot be assumed, such as interplanetary networks, military/tactical networks, disaster/emergency networks, and some forms of ad hoc sensor/actuator networks.
- Energy Harvesting/Scavenging:** Methodologies and techniques to be implemented in mobile devices to make them able to collect energy from the environment without intervention of any external operator.
- Geographic Routing:** Routing protocols that use the nodes' location (i.e., geographical coordinates) for data forwarding. They are also known as location-aware routing protocols.
- Infrastructure-Based Network/Systems:** Wireless network/system with a preinstalled fixed infrastructure. Mobile devices access the fixed infrastructure through access points.
- In-Network Processing:** General technique used in sensor networks to reduce the amount of information flowing into the network (from sensor nodes to the sink), thus reducing energy consumption associated with data transmission.
- Mesh Network:** A multihop ad hoc network that uses dedicated nodes (called *mesh routers*) communicating wirelessly to construct a *wireless backbone* that has a (limited) number of connections with the wired Internet. Mobile users obtain a multihop connectivity to the Internet by connecting to the closest mesh router.
- Mobile Ad Hoc Network (MANET):** Ad hoc network in which the source and destination nodes are not within the transmission range of each other. Communication occurs through intermediate nodes. Nodes in a MANET thus act as nodes and router at the same time.
- Opportunistic Network:** Heterogeneous multihop ad hoc network that exploits any contact opportunity to forward data. Forwarding is performed by

opportunistically exploiting the network interfaces (wired and wireless) that a node has. When no forwarding opportunity exists (e.g., there are no other nodes in the transmission range, or neighboring nodes are considered not useful for that communication), a node locally stores the messages. This type of network is suitable for sparse and frequently disconnected networks.

Pervasive Computing: A computing paradigm that refers to a scenario in which the environment is saturated with intelligent devices. User personal devices interact with external devices in a transparent way.

Power/Energy Management: Methodologies and tools aimed to efficiently manage the energetic resource of mobile devices.

Sensor Network: A network of sensor nodes are densely and randomly deployed inside the area in which a phenomenon is being monitored. Each sensor node delivers the collected data to one (or more) neighbor node, one hop away. By following a multihop communication paradigm, the data are routed to a special node (sink) and, through this, to the user.

Sensor Node: Tiny device with computing, wireless communication, and sensing capabilities that can be used for various purposes. Typical sensing tasks could be temperature, light, sound, and so forth.

Sink Node: A special node used in sensor networks to collect information acquired by sensor nodes.

Underwater Sensor Network: A sensor network used in underwater environments. For communication, it uses acoustic signals instead of radio signals.

Vehicular Networks: Mobile ad hoc networks used for car-to-car communication. Cars located between the source and destination cars operate as traffic relays.

WiFi Hotspot: Public place in which an access point is available that allows mobile devices to access the Internet. WiFi hotspots are typically available at airports, railway stations, hotels, malls, and so forth.

INTRODUCTION

Wireless ad hoc networks are a category of wireless networks that utilize multihop packet relaying yet are capable of operating without any infrastructure support (Perkins 2001; Ram Murthy and Manoj 2004; Toh 2002). Applications that necessitate ad hoc networking capabilities include mobile, collaborative, and distributed computing; mobile access to the Internet; wireless mesh networks; military applications; emergency response networks; and others. Ad hoc networks are formed by a number of devices, possibly heterogeneous, with wireless communication capabilities that connect and disconnect at will. In addition, some of these devices may be mobile and are thus able to change their location frequently. Ad hoc networks with mobile nodes are often referred to as *mobile ad hoc networks* (MANETs). Even without mobility, nodes can join or leave an ad hoc network at will, and such networks

need to possess self-organizing capability in terms of media access, routing, and other networking functions. As such, the design and deployment of wireless ad hoc networks presents several challenges that do not exist, or exist in rather different forms, in traditional wired networks. Some of the most important challenges are as follows:

- *Self-organization, adaptability, and self-healing.* The trademark feature of ad hoc networks is the ability of individual nodes to attach to and detach from such networks at will and in the absence of any fixed infrastructure. Therefore, such networks need protocols that can support and facilitate the tasks of topology construction, reconfiguration, and maintenance, as well as routing, traffic monitoring, and admission control. Note that the above constraint does not mean that an infrastructure, if present, cannot or should not be used; it just means that

the network ought to be able to function with or without such infrastructure. Furthermore, as sudden departures or even failures of individual nodes are to be expected in many applications, the network should possess self-healing capabilities so as to continue to function.

- *Scalability* of the network refers to its ability to retain certain performance parameters regardless of large changes in the number of nodes deployed in that network. Scalability is an important aspect of ad hoc networks, and it is closely related to the self-organizing property. Scalability is highly dependent on the amount of overhead in terms of bandwidth and power expenditure needed to exchange control packets at various layers (*medium access control*, or MAC; routing and transport, etc.) of network functionality. It is also affected by the manner in which the network is organized, as will be seen in subsequent discussion.
- *Delay* considerations are of crucial importance in certain types of applications—for example, in military applications such as battlefield communications or detection and monitoring of troop movements, or in health care applications where patients with serious and urgent medical conditions must be continuously monitored for important health variables via ECG, EEG, or other probes. Low delays can be achieved by bandwidth reservation requested by the source device through some kind of admission control that will monitor and prevent network congestion or by some kind of scheduling. In the latter two cases, control is exerted by some device that performs the role of network coordinator or base station. (Such a role can be, and often is, temporary.)

We stress that providing prescribed delay bounds is a nontrivial issue in traditional wired networks. In a network with nonstationary topology formed by mobile, resource-constrained nodes, maintaining the delays within prescribed bounds is even more complex. As a minimum, we might just try to reduce the delays—but this is not an easy task either. Delay minimization is often hampered by the instability of the network topology as well as by fluctuations in traffic characteristics. As a result, any minimum that may be achieved is likely to be of an ephemeral character, and constant monitoring and minimization of delays is necessary.

- *Throughput*. In some applications, the most important performance target is throughput rather than delay. Such is the case in several collaborative, distributed computing applications and in mobile access to the Internet, which might include significant amounts of multimedia traffic. At the physical (PHY) level, throughput may be impaired by packet errors caused by noise and interference. At the MAC level, throughput may be impaired by collisions if a contention-based medium access mechanism is used, or by unfairness if bandwidth reservation or scheduling-based access mechanism is used. (Detailed descriptions of these mechanisms can be found below.) Cross-layer optimization that accounts for those effects—preferably, all of them—may be needed to achieve high throughput.
- *Packet and data losses*. Loss of information is not tolerated in ad hoc networks, and active measures to restore

reliability of data transfers must be undertaken at both the MAC and upper layers.

- *Fairness*. In most cases where throughput is the most important performance indicator, fairness among different nodes or users is also of importance. Again, the instability of topology and the nonstationary traffic characteristics tend to make this problem much more difficult in wireless ad hoc networks than in traditional wired networks.
- *Power management*. Some of the nodes in an ad hoc network might operate on battery power, in which case power-management functions become necessary. Although energy efficiency is a desirable feature in general, it is seldom a crucial issue in ad hoc networks. The power source either has sufficient capacity (e.g., a car battery can be expected to provide ample medium access in ad hoc and sensor networks capacity to operate a laptop) or may be recharged as needed (e.g., when using a PDA device at home or in the office). Cases in which the minimization of energy consumption becomes the main limiting parameter for a wireless device are not too common.
- *Low maintenance*. Finally, all maintenance tasks in ad hoc networks should be automated or (at worst) be simple enough to be undertaken by nonspecialist human operators such as owners of laptop computers and PDAs. This requirement might be considered as an extension (or perhaps generalization) of the requirement for self-organizing capabilities mentioned above.

MAC Design Goals in Ad Hoc Networks

The MAC protocol is that part of the overall network functionality that deals with problems of achieving efficient, fair, and dependable access to the medium shared by many different devices (Stallings 2002). The role of the MAC protocol is particularly important in wireless networks that differ from their wired counterparts in many aspects. The most important among those differences stem from the very nature of the wireless communication medium, where two devices need not be explicitly connected to be able to communicate; instead, it merely suffices that they are within the radio transmission range of each other.

For example, when two or more packets are simultaneously received, the receiver may encounter problems. At best, the unwanted packets are treated as noise that impairs the reception of the packet intended to be received but can be filtered out. At worst, the correct packet may be damaged beyond repair and the receiver may be unable to make any sense out of it; this condition is referred to as a *collision*. Collisions waste both network bandwidth and power resources of individual devices, transmitters, and receivers alike, and active measures should be taken to reduce the likelihood of their occurrence.

Common approaches for collision minimization in wired networks include detection and avoidance. Collision detection is widely used in wired networks, where it involves the simple act of listening while transmitting. However, this is not feasible in wireless communication, where few devices are equipped with the required capability

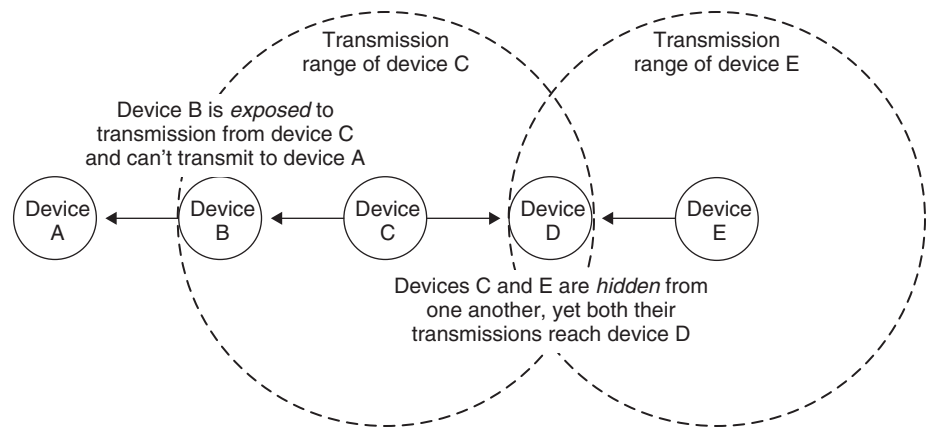

Figure 1: Hidden and exposed terminal problem

(Stallings 2002). Furthermore, packet collisions in wireless networks may occur in scenarios that cannot occur in wired ones. Two of the most common scenarios—commonly referred to as the *hidden* and *exposed terminal problems*, respectively—are depicted in Figure 1. Let us assume that the network contains five identical devices or nodes A, B, C, D, and E, and that the distances between the pairs A and B, B and C, C and D, and D and E are equal and just a bit smaller than the transmission range of each node.

- The hidden terminal problem occurs when the nodes C and E simultaneously start transmission toward node D. They cannot hear each other's transmission (they are hidden from each other), but node D can hear both of them and it senses a collision on the medium.
- The exposed terminal problem is experienced by node B, which wants to transmit a packet to node A. However, on checking the medium, node B overhears the transmission from C, even though it is not the intended recipient, and must defer its transmission for a while. At best, it has to wait until C finishes its transmission. Time and bandwidth are thus wasted because there can be no collision at A, which cannot hear transmissions from C.

The hidden and exposed terminal problems are particularly harmful because some of the offenders may be entirely unaware of them; as a result, such conditions are difficult to control and prevent. Both problems become even more complex if different nodes transmit at different power levels and thus have different transmission ranges. It should come as no surprise that these problems are addressed—with a varying degree of success—by virtually all of the MAC protocols for wireless ad hoc networks.

Because collision detection is not available, MAC protocols for wireless networks must rely on collision avoidance techniques (including explicit scheduling, bandwidth reservation, and listening to the medium) *before* attempting to transmit a packet. This last procedure is commonly known as clear *channel assessment* (O'Hara and Petrick 1999; IEEE 2003a, 2003b), although other terms may be occasionally encountered as well.

Obviously, MAC protocols in wireless networks face both traditional challenges encountered in wired networks and new ones that stem from the use of the wireless

communication medium. The most important features of MACs in ad hoc wireless networks can be summarized as follows (Ram Murthy and Manoj 2004):

- The operation of the protocol should be distributed, preferably without a dedicated central controller. If the use of such a controller cannot be avoided, then the role should be only temporary, and devices with appropriate capabilities must be allowed to undertake it for a certain period of time.
- The protocol should be scalable to large networks.
- The available bandwidth must be utilized efficiently, including the minimization of packet collisions and minimization of the overhead needed to monitor and control network operation. In particular, the protocol should minimize the effects of hidden and exposed node problems.
- The protocol should ensure fair bandwidth allocation to all the nodes. Preferably, the fairness mechanism should take into account the current level of congestion in the network.
- The MAC protocol should incorporate power-management policies to minimize the power consumption of the node and of the entire network.
- The protocol should provide *quality-of-service* (QoS) support for real-time traffic wherever possible. Real-time, in this context, implies data traffic with prescribed performance bounds; these may include throughput, delay, delay jitter, and other performance indicators.

Two additional issues deserve mention. The first issue is time synchronization among the nodes, which is required for the purpose of bandwidth reservation and allocation. Time synchronization is usually achieved by having one of the nodes periodically broadcast some sort of synchronization signal (the *beacon*), which is then used by other nodes. Although the use of periodic beacon transmissions facilitates the process of placing the reservation requests and subsequent broadcasting of reservation allocations, it requires that some node is capable of, and willing to, act as the central controller—which is somewhat contrary to the distributed, self-organizing character of an ad hoc network. In particular, additional provisions must be made to replace the controller node when it departs from

the network or experiences a failure; this is part of the self-healing property of ad hoc networks described above. Furthermore, the use of beacons consumes the bandwidth and affects the scalability of the MAC algorithm.

The second issue is related to the interference from neighboring nodes. As this interference is harmful, steps have to be taken to reduce it, most often through appropriate multiplexing techniques. According to Stallings (2002), multiplexing techniques are available in the following domains:

- in the frequency domain (i.e., through frequency division multiple access), wherein different frequency bands are allocated to different devices or subnetworks;
- in the code domain (i.e., through code division multiple access), wherein different devices use different code sequences;
- in the time domain (i.e., through time division multiple access), wherein different devices transmit at different time; or
- in the space domain, where the range and scope of transmissions is controlled through the use of transmitter power control and directional antennae, respectively.

Strictly speaking, all of these techniques belong to the PHY layer, and they are reviewed in greater detail in some of the earlier chapters. Although the MAC layer is completely oblivious to the first two techniques, it can utilize the latter two (multiplexing in time and space domain) or even integrate them to a certain extent. (For example, time multiplexing is a close relative of scheduling.) This cross-layer integration and optimization allows the MAC protocol to better address the requirements outlined above. We note that such integration is not too common in ad hoc networks, where the MAC layer is more likely to cooperate with the network (and possibly transport layers above it) than with the PHY layer below; still, MAC protocols exist that make use of it, as will be explained later.

CLASSIFICATION OF MAC PROTOCOLS FOR AD HOC NETWORKS

Before we present some of the important MAC protocols for wireless ad hoc networks, we will give a brief overview of possible criteria for classifying those protocols; the reader will thus be able to grasp main features of different MAC protocols and identify the important similarities as well as differences among them.

Mechanism for Accessing the Medium

Probably the most intuitive among the classification criteria is the manner of accessing the medium, which comes in the following three main flavors:

- *contention-based protocols* are those in which a potential sender node must compete with all others in order to gain access to the medium and transmit its data;
- *Bandwidth reservation-based protocols* in which provisions exist for requesting and obtaining bandwidth (or time) allocations by individual senders; and

- *scheduling-based protocols* in which the transmissions of individual senders are scheduled according to some predefined policy that aims to achieve one or more of the objectives outlined above, such as the maximization of throughput, fairness, flow priority, or QoS support.

Note that the third option requires the presence of an entity that is responsible for implementing the aforementioned policy. In most cases, this requirement translates into the requirement for a permanent or temporary central controller. Note also that the policy to be pursued should be adaptive, depending on the traffic or other conditions in the network. The presence of a central controller is also sometimes needed in protocols that use the second option.

Quite a few among the existing MAC protocols offer more than one of those mechanisms. This may be accomplished by slicing the available time into intervals of fixed or variable size, which are referred to as *cycles* or *superframes* (O'Hara and Petrick 1999; IEEE 2003a, 2003b), and assigning certain portions of those intervals to different categories of access from the list above. For example, the IEEE 802.11 *point coordinator function* (PCF) uses superframes in which the first part is reserved for (optional) contention-free access, while the second part is used for contention-based access (ANSI/IEEE 1999; O'Hara and Petrick 1999). A similar approach is adopted in the IEEE 802.15.4 protocol in its beacon-enabled, slotted *carrier sense multiple access with collision avoidance* (CSMA/CA) mode (IEEE 2003b), except that the contention access period precedes the contention-free period in the superframe.

On the other hand, some MAC protocols offer optional features that modify the manner in which the protocol operates and effectively introduce a different mechanism for medium access control. For example, the IEEE 802.11 *distributed coordinator function* (DCF) utilizes pure contention-based access in its default form but allows bandwidth reservation on a per-packet basis through the optional *request-to-send, clear-to-send* (RTS-CTS) handshake (ANSI/IEEE 1999).

Alternative Classifications on the Basis of Medium Access Mechanism

An alternative classification criterion could be devised by assuming that contention-based access will always be present and then using the presence or absence of the latter two access mechanisms as the basis for classification. This approach results in the common (and marginally more practical) classification into pure contention-based MACs, contention-based MACs with reservation mechanisms, and contention-based MACs with scheduling mechanisms (Ram Murthy and Manoj 2004). A variant of this approach distinguishes between contention-based or random access-based protocols, scheduling or partitioning ones, and polling-based ones. Yet even these classifications are neither unambiguous because the presence of optional features outlined above leads to the same protocol being attached to more than one category nor comprehensive because some of the existing protocols cannot be attached to any single category (Ram Murthy and Manoj 2004). Because of these shortcomings, it is listed as an alternative only.

Mechanism Used for Bandwidth Reservation and Its Scope

These two criteria apply only to MAC protocols that employ some form of bandwidth reservation and thus actually represent subclassifications within the previous one based on the mechanism used to access the medium. With respect to the mechanism used for bandwidth reservation, we can distinguish between the protocols that use some kind of handshake (e.g., RTS-CTS) and those that use out-of-band signaling, most notably the *busy tone approach*, which is an extension of the familiar concept from the traditional telephony systems.

With respect to the scope of bandwidth reservation, we can distinguish between the protocols that request bandwidth for a specified time (i.e., for a single packet or for a group of consecutive packets, commonly referred to as a *burst*) and those that request bandwidth allocation for an unspecified time. In both cases, time can be measured in absolute units or in data packets. In the former case, bandwidth allocation is valid for the transmission of a specified number of packets only; in the latter case, it has to be explicitly revoked by some central authority or perhaps waived by the requester itself.

Another scheme based on the concept related to bandwidth reservation is the family of the so-called multichannel MAC protocols. Most communication technologies use only one channel out of several available in the given frequency band. Multichannel MACs exploit this feature to employ channel hopping in order to improve bandwidth utilization or reduce congestion.

Presence and Scope of Synchronization

The presence or absence of time synchronization among the nodes in the network is another criterion that can be used to classify MAC protocols for wireless ad hoc networks. Synchronization, if present, may need to be extended to all of the nodes in the network (*global synchronization*); alternatively, it may apply to just a handful of nodes that are physically close to one another (*local synchronization*). In the former case, a central controller may be needed to initiate and broadcast the necessary synchronization information.

Synchronization is most often linked to scheduling and bandwidth reservation, because basic synchronization intervals are often used to apportion the available bandwidth to appropriate sender nodes. However, bandwidth reservation and allocation can be accomplished in an asynchronous manner, in particular when reservation is requested on a per-packet basis, whereas synchronous protocols can be used even with pure contention-based access. For example, the IEEE 802.15.4 protocol in its beacon-enabled, slotted CSMA/CA mode without guaranteed time slots uses pure contention-based access, yet all transmissions must be synchronized to the beacon frames periodically sent by the network coordinator (IEEE 2003b).

Synchronization is one of the most important factors that may affect scalability of the network. As the size of the network grows, synchronization becomes more difficult and more costly to establish and maintain. In particular,

protocols that rely on global synchronization will suffer the most degradation; for example, it has been shown that the construction and maintenance of a globally optimal schedule in a multilevel Bluetooth network (a *scatternet*) is a nondeterministic polynomial time-complete problem (Johansson, Körner, and Tassiulas 2001).

Presence and Permanence of a Controller

Another possible classification criterion is the presence and permanence of a central network controller or coordinator. Whereas wireless ad hoc networks by default should be able to function without a permanent or dedicated central controller, quite a few protocols rely on certain monitoring and control functions that can only be provided by a local or global controller. This is the case with several of the MAC protocols that use bandwidth reservation, as well as with all of the MAC protocols that use scheduling. In fact, even some pure contention-based protocols rely on the presence of a controller for administrative tasks such as time synchronization and sometimes even node admission. Again, the presence of a controller affects the scalability of the network because the amount of work the controller has to do—most of which is administrative and control overhead—must grow with the number of nodes. Hierarchical decomposition or layering is often used to reduce this overhead, but it leads to additional problems in synchronization and delays.

Interference Reduction Mechanism

With respect to the interference reduction mechanisms mentioned above, a clear-cut classification may be hard to define. Multiplexing in the time domain (i.e., through *time-division multiple access*, or TDMA) effectively means that the MAC protocol utilizes some kind of scheduling or, at the very least, bandwidth reservation. As a result, any classification based on the use of TDMA techniques is effectively a replication of the first classification above—that is, the one based on the mechanism for medium access control.

However, the use (or absence) of techniques for space domain multiplexing can still be useful as a criterion for classifying the MAC protocols, in which case we can distinguish among:

- protocols that do not use any form of multiplexing in the space domain,
- protocols that use power control to limit the transmission range, and
- protocols that use directional antennae to limit the scope of their transmissions.

We note that the second and third categories are not mutually exclusive and MAC protocols exist that use one or the other multiplexing technique—or both at the same time.

Interdependence of Classification Criteria

As can be seen, not all of the classification criteria outlined above are entirely independent of each other; rather, they exhibit a certain overlap or redundancy. Still, they are

useful in the study of MAC protocols because they tend to highlight different aspects of their design and operation. In the discussions that follow, we will look at the MAC protocols in the following order: contention-based protocols; protocols that use bandwidth reservation; protocols that use multiple channels, out-of-band signaling, and directional antennae; and protocols that use polling.

CONTENTION-BASED MAC PROTOCOLS

Basic Carrier Sense Multiple Access

Most of the MAC protocols are derived from the basic *carrier sense multiple access* (CSMA) mechanism (Bertsekas and Gallager 1991). CSMA is a pure distributed protocol without centralized control, which operates as follows. The node that wants to transmit a packet first performs the clear channel assessment procedure—that is, it listens to the medium for a prescribed time. If the medium is found to be clear (or idle) during that time, then the node can transmit its packet. Otherwise—that is, if another transmission is in progress—the node backs off by waiting for a certain time before undertaking the same procedure again.

Different MAC algorithms use different ways to calculate the time they need to listen to the channel during the clear channel assessment procedure and to calculate the time to wait (i.e., the duration of the backoff period) before the next transmission attempt.

It is possible that the transmissions from two or more nodes overlap in time, which results in a collision and loss of all packets involved. If lossless communication is desired, collisions must be detected so that the lost packets can be retransmitted. Because a collision can be detected only at the receiver side, some form of acknowledgment from the receiver may be needed; some MAC protocols provide this facility, whereas others leave it to some of the upper layers (most likely, the transport layer). The former approach is more efficient in terms of reaction time, whereas the latter allows for much simpler implementation of the MAC protocol used.

In the basic CSMA protocol, carrier sensing is performed only at the sending node. Therefore, the hidden terminal problem is still present. Moreover, the exposed terminal problem leads to deferred transmissions and thus reduces bandwidth utilization.

We note that a separate chapter is devoted to the details of the CSMA protocol.

IEEE 802.11 MAC

Strictly speaking, the IEEE 802.11 protocol (O'Hara and Patrick 1999) is intended for *wireless local area networks*

(WLANs) rather than wireless ad hoc networks. However, it is interesting to examine it in some detail, mainly on account of its ubiquity, and because it uses most of the main concepts that are reused in many MAC protocols for ad hoc networks. The protocol covers the functional areas of access control, reliable data delivery, and security; in the following we will focus on the first two areas, as the last one (security) is beyond the scope of this chapter.

Reliable transfer is achieved through the use of *acknowledgment* (ACK) packets or frames, sent by the destination node upon successful data-packet reception. Medium access is regulated in two ways, the first of which is a distributed contention-based mechanism known as the *distributed coordination function*, which does not require a centralized controller. The DCF, based on the CSMA protocol described above, operates as follows. The node that wants to transmit a packet first performs the clear channel assessment procedure—that is, it listens to the medium for a time equal to the *interframe space* (IFS). If the medium is found to be clear (or idle) during that time, then the node can transmit its packet immediately; otherwise—that is, if another transmission is in progress—the node waits for another IFS period. If the medium remains idle during that period, the node backs off for a random interval and again senses the medium. During that time (referred to as the *backoff window* or *contention window*), if the medium becomes busy, the backoff counter is halted; it resumes when the medium becomes idle again. When the backoff counter expires and the medium is found to be idle, the node can transmit the packet.

A possible scenario in which this procedure is applied is schematically depicted in Figure 2. There are several points worth mentioning. First, the backoff interval is chosen as a random number from a predefined range. After each collision, the range is doubled to reduce the likelihood of a repeated collision. After each successful transmission, the range is reset to its initial value, which is typically small. This approach is known as *binary exponential backoff* (BEB) (Stallings 2002). In this manner, the protocol ensures a certain level of load smoothing in case of frequent collisions caused by heavy traffic.

Second, to enhance reliability and avoid the hidden and exposed terminal problems to a certain extent, the RTS-CTS handshake—well known from wired communications—may optionally be used. In this case, the node that wants to send a data packet first sends a request-to-send packet to the designated receiver; if ready, it responds with a clear-to-send packet. Both RTS and CTS packets contain information about the duration of the forthcoming transmission, including the optional acknowledgment. Once the sender receives the CTS packet, it may begin actual data transmission, which may optionally be followed by an ACK packet. The RTS-CTS handshake constitutes a

Figure 2: Basic access method in IEEE 802.11 DCF

simple form of bandwidth reservation on a per-packet or per-group basis, as will be explained below.

Reliability of transmission is enhanced because the RTS and CTS packets are generally much shorter than data packets; if they collide, the time waste is not high, but the risk that subsequent data packets will experience a collision is substantially reduced. The hidden terminal problem is avoided because other nodes within the transmission range of the receiver, on hearing the CTS packet, become aware of a forthcoming data transmission and defer their transmission for the time interval specified. On the other hand, a transmission from an exposed terminal may prevent the sender from initiating the RTS-CTS handshake. However, once the sender receives a proper CTS packet, it can assume that the receiver is not affected by the interfering transmission and can thus proceed with the data-packet transmission.

Third, to ensure the proper functioning of the protocol, three different IFS intervals are used: a *short IFS* (SIFS), a medium-duration *point coordination function IFS* (PIFS), and a long-duration *distributed coordination function IFS* (DIFS). The existence of several IFS intervals of different duration actually serves to implement different priority levels for different types of access. The DIFS interval is used for ordinary asynchronous traffic, whereas the SIFS interval, being the shortest, is used in the following cases:

- when the receiver sends an ACK packet on successful reception of a data packet (in this manner, ACK packets are safe from collisions because regular data packets wait longer);
- when the sender wants to send another data packet on receiving an ACK packet for a previous one (in this manner, a burst of packets commonly obtained by segmenting a longer packet from the upper layers can be delivered quickly and with little risk from collision, although such transmissions can result in unfairness because there is a limit on the duration of the burst that can be transmitted); and
- when the node sends a CTS packet on receiving a RTS packet from a prospective sender (again, the use of the SIFS interval minimizes the risk that the CTS packet will experience a collision).

The PIFS interval is used in an alternative access method known as the *point coordination function*, which is implemented on top of DCF. The PCF requires the presence of a central point coordinator, hence the name. The point coordinator defines an interval known as a *superframe*. In the first part of the superframe, the coordinator issues polls to all nodes configured for polling. The polls are sent using the regular CSMA algorithm outlined above. When a poll packet is sent, the polled node may respond using the SIFS interval. If the coordinator receives the response, then it issues another poll but using the PIFS interval. The polling continues in round-robin fashion (i.e., one node at a time) until all of the nodes are polled. Then the point coordinator remains idle until the end of the superframe, which allows for DCF-style contention-based access by all other nodes. The structure of the PCF superframe is schematically shown in Figure 3. The duration

Figure 3: Superframe structure with IEEE 802.11 PCF

of the superframe is fixed, but an ongoing transmission may force the coordinator to defer the beginning of a polling cycle; in this case, the useful duration of the superframe will be reduced.

Although the IEEE 802.11 DCF is able to deal with asynchronous traffic, the presence of synchronous traffic with specified (and reasonably stable) throughput over prolonged periods of time is well served by its PCF counterpart. Still, the PCF functionality is designated as an optional facility in the 802.11 standard (ANSI/IEEE 1999), and it is rarely used in practice.

Multiple Access Collision Avoidance

One of the pioneering attempts to define a MAC protocol for ad hoc networks is the *multiple access collision avoidance* (MACA) protocol described by Karn (1990). Similar to the 802.11 DCF, the MACA protocol uses the three-way handshake with RTS and CTS packets preceding the data-packet transmission; but unlike the 802.11 protocol, MACA does not use carrier sensing. The sender initiates the handshake with a RTS packet, to which the receiver should respond with a CTS packet. Once the sender receives the CTS packet without errors, it commences the transmission of the data packet. If a packet is destroyed through a collision, the sender undertakes a backoff procedure using the BEB algorithm. Figure 4 depicts the operation of the MACA protocol. Note that explicit acknowledgments of successful data-packet transmissions are not used in this protocol.

Both RTS and CTS packets contain information about the duration of the data transmission. Nodes in the vicinity of the sender, such as node A in Figure 4, hear the RTS packet and defer the transmission of their packets so that the sender can receive the CTS packet. Nodes in the vicinity of the receiver (node B in Figure 4) hear the CTS packet and defer the transmission of their packets so that the receiver can receive the data packet. In this manner, both the hidden and exposed terminal problems are avoided—to a certain extent, because the risk of collisions is reduced but not entirely eliminated—and RTS and CTS packets can still collide. However, the exponential backoff used in the MACA protocol creates the risk of a different yet equally severe problem—namely, that of unfairness, which can quickly lead to starvation under heavy loads.

As an example, consider the network that consists of two sender and two receiver nodes, positioned in the manner schematically depicted in Figure 5. Let both senders 1 and 2 generate a high volume of traffic, and let sender 1 capture the medium first and start transmitting packets. Because of random timing of packet transmissions, a number of

Figure 4: Timing diagram of the control handshake in the MACA protocol

Figure 5: Collisions of data and RTS packets can cause starvation in the MACA protocol

Figure 6: Collisions of data and CTS packets can cause starvation in the MACA protocol

packets from sender 2 may experience collisions. Because receiver 2 does not send proper CTS packets, sender 2 backs off repeatedly—but the backoff window keeps getting longer and longer because of the BEB algorithm. As a result, sender 2 is starved—that is, it is effectively blocked from accessing the medium.

Several variations of this problem occur in different scenarios. Consider, for example, the network with two senders and two receivers, shown in Figure 6, in which an exposed node (sender 2) is able to hear the transmissions from sender 1 but not those from receiver 1. Thus, it is free to commence its handshake while sender 1 transmits a data packet to the receiver 1. Sender 2 sends a RTS packet to receiver 2 which responds with a CTS packet, which in turn collides with the data packet from sender 1. Because the sender 2 does not receive a CTS packet, it will keep increasing its backoff window unnecessarily and effectively starve in the process.

A similar scenario is shown in Figure 7, where sender 2 is within the transmission range of receiver 2 but beyond the transmission range of sender 1. If sender 2 transmits data to receiver 2, then receiver 1 is able to hear those transmissions and unable to respond to the RTS packet sent by sender 1. Because sender 1 does not get any response (i.e., CTS packets) to its RTS packets, it concludes that there are collisions and effectively starves by continually increasing its backoff window.

Figure 7: An exposed receiver can lead to starvation of a remote sender in the MACA protocol

Multiple Access Collision Avoidance Protocol for WLANs

To alleviate the problems of the MACA protocol, Bharghavan et al. (1994) have proposed several modifications to it; the improved protocol is known as *multiple access collision avoidance protocol for WLANs* (MACAW). The bulk of those modifications attempt to solve the starvation problems, most notably those caused by unfairness. An obvious solution is to somehow balance the backoff windows of neighboring nodes, which should result in balancing their respective probabilities to access the medium. First, modification consists of augmenting the packet header with an additional field that contains the current value of the backoff counter of the transmitting node. A node that receives the packet reads and copies it into its own backoff counter. In this manner, the backoff windows of the nodes will tend to have similar values.

Second, modification aims to avoid the rapid increase of the duration of the backoff window. The reader will recall that the original BEB algorithm prescribes that the range within which a random value is chosen for the backoff window is to be doubled after each collision and reset to the initial value after a successful transmission. As a result, the duration of the backoff window can exhibit rather large and abrupt variations. Instead, the MACAW algorithm uses the so-called multiplicative increase, linear decrease backoff mechanism. In this approach, a collision causes the backoff counter to be increased by a constant factor—for example, the value of 1.5 is typically used—whereas a successful transmission simply decrements the backoff counter by one. In this manner, the backoff counter changes much less abruptly, and long contention windows after unsuccessful transmissions are avoided.

Starvation of an exposed node is addressed through the introduction of a small control packet designated as a *data-sending* (DS) packet; this packet is sent immediately before the actual data packet. The corresponding timing diagram is shown in Figure 8, where nodes A and B defer their transmissions because of a pending data packet from sender to the receiver—although B learned about it from the CTS packet and A learned about it through the DS packet.

Another change introduces per-flow fairness instead of per node, as is the case in MACA. When several data flows originate at a single node, separate queues are maintained for each flow and the backoff procedure is performed independently for each queue. When a node has one or more packets ready for transmission, then it chooses the queue for which the backoff window is the shortest.

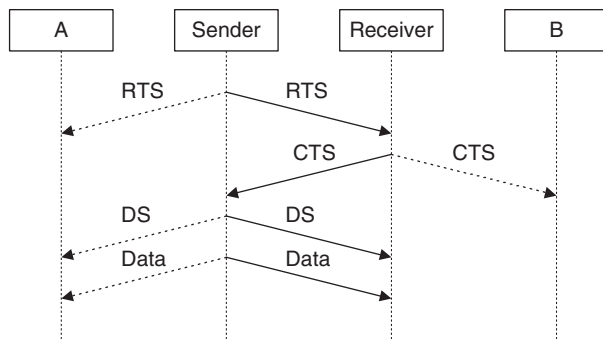

Figure 8: The role of the DS packet in the MACAW protocol

As mentioned above, the MACA protocol does not use acknowledgments, and reliable transport is the responsibility of the transport layer. However, most implementations of the TCP protocol use long time-out delays—on the order of hundreds of milliseconds—to be able to accommodate a wide range of transmission delays. Correction of erroneous or lost packets thus incurs substantial delays. To reduce those delays, the MACAW protocol introduces explicit ACK packets that are sent by the receiving node on successful reception of a data packet. If the ACK packet is missing, then the sender will attempt to retransmit the same packet, only this time with an increased value of the backoff counter. It retransmits the RTS packet for the same data packet. Now if the data packet was not correctly received the first time, the entire transmission cycle is repeated. However, if the data packet was correctly received (which means that the ACK packet was lost, most likely because of a collision), the receiver responds with the appropriate ACK packet instead. This informs the sender that the original data transmission was successful, and the sender may move on to the next data packet.

Another modification addresses the scenario depicted in Figure 7. This type of starvation is alleviated through the use of another control packet known as *request to request to send* (RRTS). In other words, when receiver 1 receives a RTS packet to which it cannot respond, it sends a RRTS packet to sender 1 in the next contention period. Neighboring nodes that hear this packet—including sender 2—are obliged to remain silent for two successive RTS–CTS cycles, which gives sender 1 sufficient time to retransmit its RTS packet and receive the corresponding CTS packet. In this manner, the remote sender is able to conclude the data-packet transmission without starvation. Figure 9 shows the corresponding timing diagram.

Floor Acquisition Multiple Access

Fullmer and Garcia-Luna-Aceves (1995) have proposed a family of protocols known as *floor acquisition multiple access* (FAMA) that generalize the approach based on CSMA access with the control packet handshake. In this sense, both the MACA and MACAW protocols belong to the FAMA family.

The basic concept behind the FAMA protocols is that the sender node has to acquire the floor before attempting to transmit its data. This is accomplished through the control packet handshake. Although control packets themselves may suffer collisions, the protocols ensure that the data-packet transmission is collision-free. The original proposal

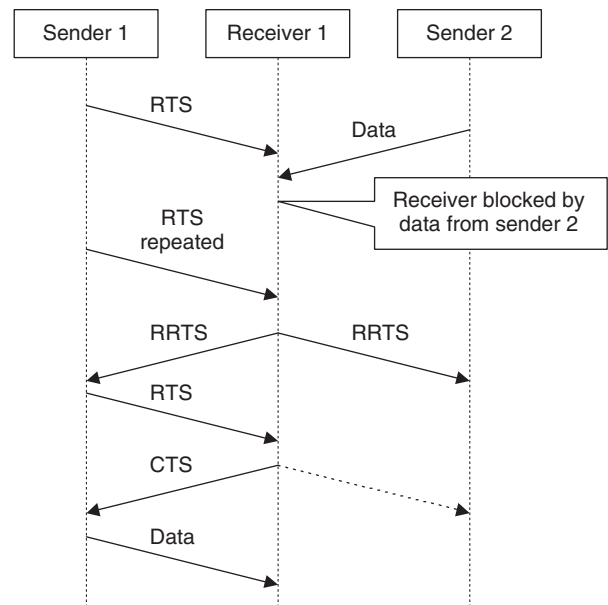

Figure 9: The role of the RRTS packet in the MACAW protocol

(Fullmer and Garcia-Luna-Aceves 1995) discusses several variants of the FAMA protocol and derives the timing relationships and constraints that allow it to achieve collision-free data transmission. In this process, the round-trip propagation time of the channel is used to derive the waiting times at particular steps in the protocol.

Another interesting feature of the FAMA protocols is that some among them allow the sender to use a single control RTS–CTS handshake before sending a packet burst, similar to the 802.11 DCF protocol. In this case, the bandwidth utilization is improved because the overhead incurred by the control handshake is shared by all of the packets in the burst.

MACA by Invitation

Talluci, Gerla, and Fratta (1997) have adopted a different approach that aims to reduce the number of control packets (and, by extension, the overhead thus incurred); this protocol is known as *MACA by invitation* (MACA-BI). The main change from the original MACA protocol is that data transmission can be initiated by the receiver, rather than the sender. The receiver sends the *ready to receive* (RTR) packet to the sender, which, if ready, simply responds with the data packet. The corresponding timing diagram is shown in Figure 10, where the receiver's hidden neighbor A hears the RTR packet and defers its transmission until the data packet is received. However, collisions are not eliminated altogether through this technique. In particular, RTR packets may collide with each other (for example, when two potential receivers request data from the same sender) or with data packets sent from a hidden terminal in the vicinity.

The main problem of the MACA-BI protocol stems from the fact that the receiver does not know in advance the moments of packet arrivals at the sender or the length of those packets. Instead, the receiver must estimate those values and embed the estimates in the RTR packet. To improve the accuracy of those estimates and thus increase

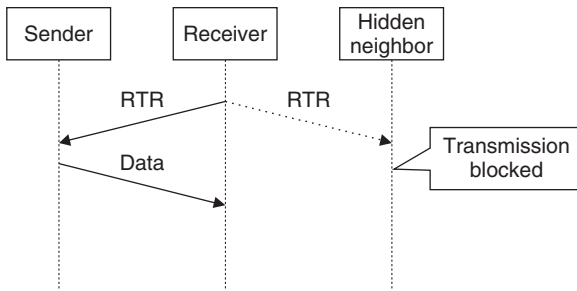

Figure 10: Receiver-initiated data-packet transmission in the MACA-BI protocol

the overall efficiency of the protocol, the format of the data packets may be modified to include control information about the data flows at the sender—for example, the number of backlogged packets queued for transmission and their individual lengths. Furthermore, the sender is allowed to initiate transmission in the usual manner—that is, by sending an RTS packet with appropriate control information.

MACA with Reduced Handshake

In many cases, the sender usually sends a burst of packets to the receiver, rather than a single packet: for example, when TCP connections are established in a wireless ad hoc network. This observation has inspired Toh et al. (2000) to devise a protocol known as *MACA with reduced handshake* (MARCH) that aims to reduce the overhead incurred by the control packet handshake. In this protocol, data-packet transmission is initiated by the sender, which sends a regular RTS packet to the receiver; the receiver responds with a CTS packet. Subsequent transmissions use only RTS packets preceding the data packets. Obviously, the more packets are transmitted in a burst, the more efficient transmission will be because the control packet overhead is shared by all of the packets in the burst.

By itself, this feature would not be worth mentioning because other protocols described above contain similar provisions. But the importance (and the main contribution) of the MARCH protocol is in its use of a reduced handshake for multihop transmissions through one or more intermediate nodes, a common scenario in wireless ad hoc networks (Toh 2002) that neither the original MACA nor its numerous variants specifically address. Consider the network with four nodes A, B, C, and D, in which data packets are sent in bursts from A to D through intermediate nodes B and C. In MACA, this transmission has to be implemented as a series of single-hop (i.e., node-to-node) transfers with the full control handshake for each hop, as shown in Figure 11. The MARCH protocol makes use of the fact that the RTS–CTS exchange between the sender and the receiver can often be heard by the next hop receiver; in our example, the control handshake between nodes A and B actually alerts the next hop receiver C to the forthcoming data transmission. Consequently, the control handshake between the nodes B and C can be simplified by omitting the RTS packets. Instead, node C can simply send the CTS packet to node B as soon as the data transmission from node A is finished. In this

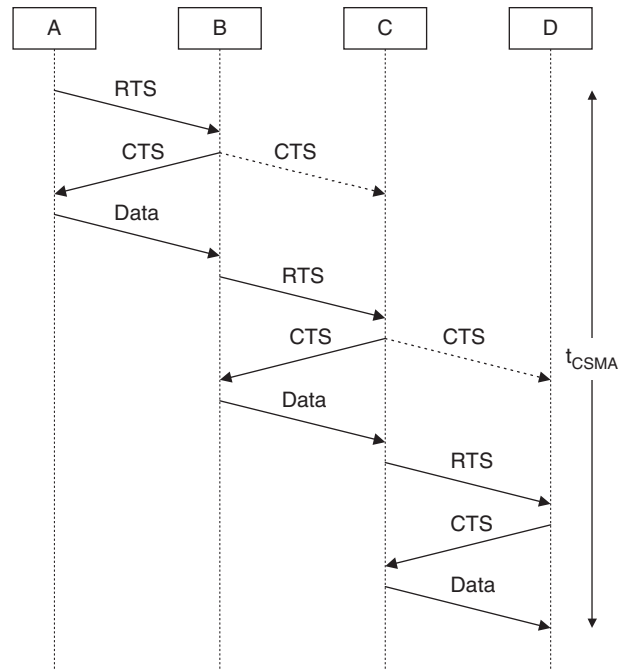

Figure 11: Multihop transmission of a packet burst in the original MACA protocol

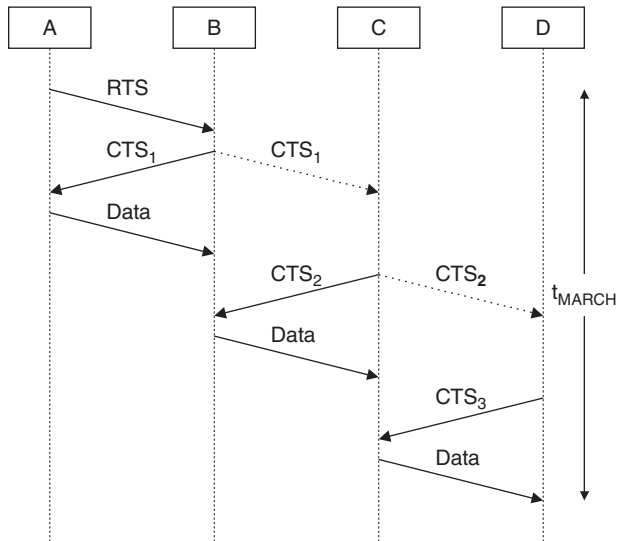

Figure 12: Multihop transmission of a packet burst in the MARCH protocol

manner, the control handshake is simplified and the associated overhead is reduced, which leads to substantial improvements in efficiency (i.e., increased throughput and reduced end-to-end delay) when compared to the original MACA or its variants described earlier. The control handshake in the MARCH protocol is shown in Figure 12.

We note that the MARCH protocol does require assistance from the routing algorithm because the CTS packets have to carry proper route identification so that the intended receiver (and only it) can issue the required CTS.

MAC PROTOCOLS THAT USE BANDWIDTH RESERVATION

Bandwidth reservation can be implemented only if some form of multiplexing in the time domain—that is, TDMA—is used. In the TDMA approach, available time is partitioned into time frames or slots that can be requested by and subsequently allocated to the nodes that have data to send. As noted above, this approach necessitates the presence of a centralized control in the form of a dedicated controller node. Time partitioning is typically done in a hierarchical manner, with smaller intervals (slots or frames) grouped into larger ones (cycles or superframes). Node transmissions are then aligned to the slot boundaries. In this manner, the controller node is able to monitor the utilization of the channel and to allocate bandwidth while taking into account QoS requirements and fairness among the nodes; bandwidth allocation also can be performed on a permanent or one-off basis.

In the area of wireless networks, the concept of bandwidth reservation was historically first exploited with satellite networks (Bertsekas and Gallager 1991) and later in wireless ATM starting with the *packet reservation multiple access* (PRMA) protocol described by Goodman et al. (1989). A nice overview of reservation techniques for wireless ATM networks can be found in the work by Sanchez, Martinez, and Marcellin (1997). We will now describe a few representative protocols that use the reservation approach in wireless ad hoc networks.

Distributed Packet Reservation Multiple Access

In the *distributed PRMA* (D-PRMA) protocol proposed by Jian et al. (2002), each frame is divided in slots, and each slot is divided into minislots, as shown in Figure 13. Each minislot can be used for data transmission or for control handshake. In the latter case, the first part of the minislot is used for the RTS packet or *busy indication* (BI) signal, while the second part is used for the CTS or BI. All nodes that have a packet for transmission must listen to the medium at the beginning of each slot. If the medium is free, they compete for access by sending the RTS packet in the RTS-BI part of the first minislot of each slot. If the node receives the CTS response in the same minislot, it can use the remaining portion of the slot (minislots 2 to m) for its transmission. If a collision occurs in the RTS-BI field, the contention process continues in subsequent minislots of the same slot until one node wins the slot.

Figure 13: Frame structure in D-PRMA protocol

Once a node wins the slot, it transmits its data in the next minislot. Transmission lasts until the end of the slot or until there is no more data, whichever is shorter. Other nodes that want to transmit will find the channel busy and have to wait. Provisions are made to eliminate the risk of collision for CTS packets (the designated receiver sends a CTS packet only if it receives a RTS packet correctly—that is, without collision), the hidden terminal problem (nodes that hear the CTS packet defer their transmission until the end of the current slot) as well as the exposed terminal problem (nodes that hear the RTS but not the CTS packet are still allowed to transmit).

The D-PRMA protocol tries to cater to the fact that nodes in an ad hoc network can carry both synchronous (voice or multimedia) and asynchronous data traffic; the former is generally delay-sensitive but much less loss-sensitive than the latter. To give priority to synchronous traffic as soon as it is generated by the application, the D-PRMA protocol introduces priorities to each node. Priority is a parameter p with a value between 0 and 1; nodes will start contending for access in a free minislot with probability p or skip it and wait for the next opportunity with probability $1 - p$. Nodes with synchronous traffic are allowed two exceptions: (1) Any such node can start the contention process in minislot 1 with the probability of 1 and (2) any such node that manages to win a slot is allowed to reserve that same slot in every frame until the end of the session. (Nodes with asynchronous traffic can win a single slot only and have to contend again for each subsequent slot.)

Reserved slots are identified through a BI signal sent by the sender (the node with synchronous traffic that has won the slot in the previous frame) in the RTS-BI portion of minislot 1, and by the receiver in the CTS-BI part of that same minislot. In this manner, other nodes learn about the reservation and do not contend for that slot in the current frame. End of the data stream and the corresponding reservation is announced simply by the absence of the BI signal.

We note that the RTS packet carries the address of its one-hop destination, and only the destination node is allowed to reply with a CTS packet. Nodes that hear the CTS packet are not allowed to transmit within the same slot. Similar to the MACA protocol, any node that hears the RTS packet but not the CTS one is allowed to transmit.

Hop Reservation Multiple Access Protocol

The *hop reservation multiple access* (HRMA) protocol utilizes multiplexing in both time and frequency domain (Tang and Garcia-Luna-Aceves 1999a). In the time domain, available time is partitioned into frames, which are in turn divided in slots. In the frequency domain, different frequencies are used for different slots; in this manner, the HRMA is effectively a variant of the well known *frequency hopping spread spectrum* (FHSS) approach (Stallings 2002). The first slot in the frame is selected as the synchronization slot, which is why it always uses the same frequency. All other slots consist of two subslots that use different frequencies from the hopping sequence. The first subslot is used for transmitting hop-reservation packets, RTS packets, CTS packets, and data packets. The second subslot is used for receiving acknowledgement packets for

the data transmission received during the previous sub-slot. The frame structure of the HRMA protocol is shown in Figure 14.

Collision Avoidance Time Allocation Protocol

The *collision avoidance time allocation* (CATA) protocol divides the frame into a number of equally sized slots (Tang and Garcia-Luna-Aceves 1999b). Each slot is divided into five minislots: The first four are control minislots, and the fifth one is the data minislots. A node that wishes to transmit data reserves the data minislots by transmitting a RTS packet in the second control minislots. The intended receiver responds with a CTS packet in the third control minislots. On receiving the CTS packet, the sending node transmits a *not-to-send* (NTS) packet in the fourth minislots; the NTS packet serves to regulate the multicast or broadcast transmission. The frame structure of the CATA protocol is shown in Figure 15.

Figure 14: Frame structure in HRMA protocol

Figure 15: Frame structure in the CATA protocol

MACA with Piggybacked Reservation

The *MACA with piggybacked reservation* (MACA-PR), originally proposed by Lin and Gerla (1999), is an example of the cross layer interaction of MAC and routing layers with two priority levels: for real-time and data packets, respectively. Communications in the MACA-PR protocol are schematically shown in Figure 16. As in many other protocols, time is divided in slots. Each node maintains the *reservation table* (RT) with all reserved slots of the nodes in its transmission range. A node that has a non-real-time packet ready for transmission will first perform carrier sensing in the slot that is labeled as free in its RT. If the channel is found to be free in that slot, then the node transmits the RTS packet and receives CTS packet. Both RTS and CTS packets contain the information about the time period needed for data-packet transmission (labeled *network allocation vector*, or NAV). The CTS packet is followed by the data packet, which is in turn followed by the acknowledgement.

For real-time traffic in which data packets are sent with known periodicity, the first packet from the stream is sent as a regular non-real-time packet. However, the reservation for the next packet is piggybacked on the current data packet. This reservation contains the time period in which the next data packet is to be transmitted. All neighbors that hear the reservation will update their reservation tables accordingly. In case of transmission failure, real-time packets are not retransmitted.

The MACA-PR protocol avoids the hidden terminal problem by periodic exchange of reservation tables. Furthermore, reservation information times out if it is not refreshed during a certain time period.

Distributed Priority Scheduling

The *distributed priority scheduling* (DPS) protocol was initially proposed by Kanodia et al. (2004). The DPS protocol assumes that nodes use the 802.11 distributed

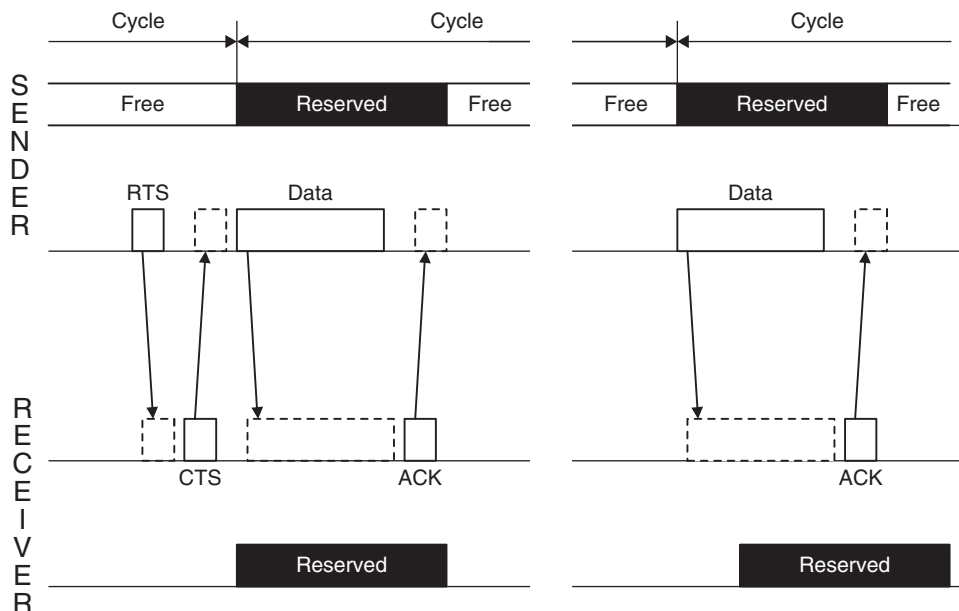

Figure 16: Communication in MACA-PR protocol

coordination function with the RTS-CTS-data-ACK handshake. Nodes send packet priority information piggybacked at the end of the RTS packet. Each node stores the information about the priority of overheard packets, and calculates its own priority relative to the nodes in the neighborhood. The receiving node will append the priority information at the CTS packet together with the sender's ID. Neighboring nodes then extract priority and node ID information from the RTS and CTS packets they have overheard and calculate their own rank relative to the neighbors. The rank is used to calculate the node back-off window according to the 802.11 DCF. For multihop communications, where end-to-end delay bounds for the packet are specified, the packet priority may change (increase) in the downstream nodes in order to meet the bound. Communication of table updates in the DPS protocol is shown in Figure 17.

MULTICHANNEL MAC PROTOCOLS

The main distinguishing feature of the protocols from the multichannel MAC protocols group is the utilization of several available channels—effectively, a form of frequency and channel multiplexing—to reduce congestion. Conceptually, this idea is not new: Many protocols apply channel partitioning—for example, 802.11 (ANSI/IEEE 1999; O'Hara and Petrick 1999) or HRMA (Tang and Garcia-Luna-Aceves 1999a)—and the FHSS variant of the CDMA approach is widely used at the physical level (Stallings 2002). But all of these protocols allocate individual channels according to a predetermined hopping sequence or a pseudo-random sequence in case of FHSS. On the contrary, multichannel MAC protocols select channels in a dynamic fashion that takes into account the current state of congestion of all of the available channels. Two main approaches are possible: (1) a dedicated channel is used for coordination and control and (2) the entire transmission (i.e., both control handshake and data) of each flow uses a different channel (Shi, Salonidis, and Knightly 2006). Although both approaches are capable of improving

throughput, they suffer from different problems. In the first, some node pairs may be unable to communicate for prolonged periods; in the second, the dedicated control channel incurs some overhead, and its capacity should be carefully determined to avoid congestion in that channel. We will now present a few of the most important multichannel MAC protocols.

Multichannel CSMA with Soft Channel Reservation

This multichannel CSMA protocol was originally proposed by Nasipuri, Zhuang, and Das (1999). It assumes that the available frequency band is partitioned into N channels, and each node monitors all N channels whenever it is not transmitting. Channels in which the total received signal strength is below a predefined threshold are marked as idle, and the time instants at which this parameter drops below the threshold are marked; remaining channels are busy. When a packet arrives, the node checks its list of idle channels to see if the last channel it used is free. If so, this channel is used to transmit the packet; if not, a channel is randomly selected from the list. If there are no free channels, the node waits for the first channel to become idle. If the selected channel has remained idle during a period of long interframe space, the node initiates the transmission; otherwise, a random backoff is undertaken. An ongoing backoff is immediately cancelled if the channel becomes busy, and a new backoff is scheduled when the channel becomes idle again. *Soft reservation* refers to the fact that the scheme obviously gives preference to the last channel that was successfully used and thus tends to reserve a channel for each node (Nasipuri, Zhuang, and Das 1999). Distributed, dynamic channel allocation allows this scheme to significantly reduce the chances of collision, even in heavy traffic conditions, but it still suffers from two major problems. At the implementation level, the radio subsystem must be sophisticated enough to monitor the received signal strength on a per-channel basis for all channels; such

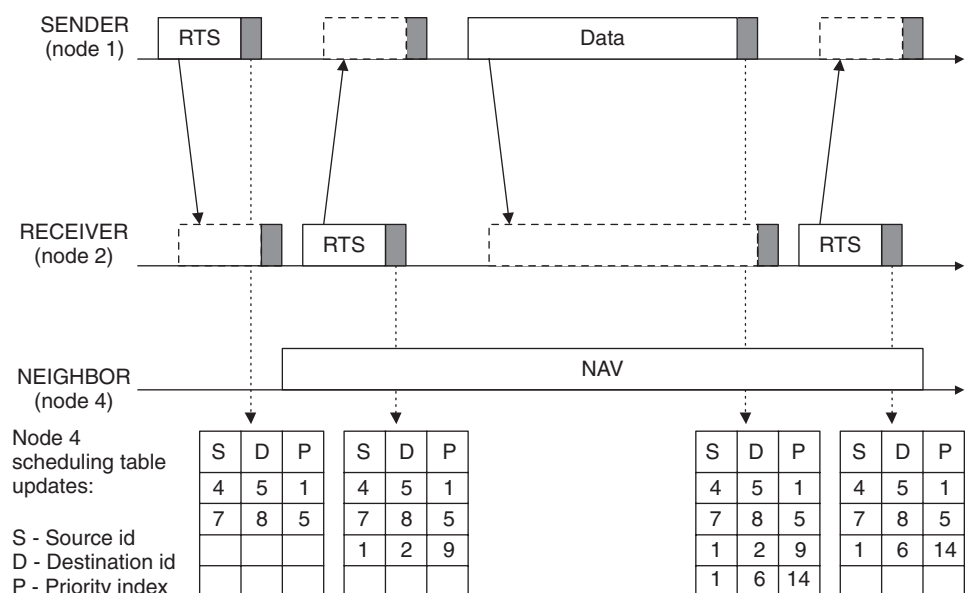

Figure 17: Packet transmission in the DPS protocol

radios are more complex and more costly. At the conceptual level, the fact that channels are selected by the transmitting node means that the scheme still suffers from the hidden terminal problem at the receiver node.

This last observation was the foundation for the improved scheme in which channel selection is performed by the receiver (Jain, Das, and Nasipuri 2001). In the improved scheme, a dedicated, shared channel is used to transmit RTS and CTS packets, which is effectively a form of out-of-band signaling (to be discussed below). A node that has a packet to send begins by sensing the state of all data channels and builds a list of free channels, much as in the original proposal. If no free channel is found, then a backoff procedure is undertaken and the sensing is repeated. Once a free channel is found, the node then sends a RTS packet via the control channel; this packet contains the transmitter's list of free channels. The receiver then forms its own list of free channels, compares it to the one supplied by the transmitted, and selects the channel to be used for actual data transmission in the following manner. If the two lists overlap, then the receiver selects the best common channel (i.e., the one with the least received signal strength and consequently the least interference); this information is sent back to the transmitter within an RTS packet. If the two lists do not overlap, then the receiver does nothing; the transmitter eventually times out and repeats the procedure after a backoff. On receiving a valid RTS packet, the data packet is transmitted on the designated data channel. Successful transmission is acknowledged on the same data channel; failure to receive proper acknowledgment triggers another backoff and repetition of the entire procedure.

It is worth noting that nodes that overhear the RTS packet do not attempt to use the designated data channel during the entire duration of data transmission. Nodes in the vicinity of the transmitter are able to hear the RTS packet but not the CTS packet; these are required to refrain from transmitting only for the duration of the CTS transmission (in fact, until the transmitter's time out) but do not have to wait until the final ACK packet. In this manner, collisions between control handshake and data packets are avoided, the hidden terminal problem is alleviated, and throughput is improved. Again, the main problem is related to the implementation of the radio subsystem capable of monitoring the state of all channels in a given frequency band.

Slotted Seeded Channel Hopping

The *slotted seeded channel hopping* (SSCH) approach was initially proposed by Bahl, Chandra, and Dunagan (2004). SSCH is a distributed protocol for making and coordinating channel switching decisions, with the main objective of improving the throughput. Although the original paper describes the implementation in the IEEE 802.11 environment, the SSCH protocol is portable to other environments as well because it can be implemented in software without any modification of the radio subsystem. In SSCH, time is partitioned into slots of 10 ms, which suffices for approximately thirty-five transmissions of packets of maximum allowed length; this value was chosen to minimize the overhead of channel switching. Each node maintains a

list of channels that will be used, as well as the times when transmissions will switch to the corresponding channels; this is referred to as the *channel schedule*. Each node also maintains, or strives to maintain, the channel schedules for all of the other nodes it is aware of. In this manner, the protocol ensures that any given pair of nodes will ultimately be able to communicate, despite the possibility of unexpected schedule changes. Channel schedules are kept in a compact form as a current channel and a rule used for updating the channel to avoid the excessive overhead needed for synchronization. The rule is actually a seed used to update the channel table, hence the name of the protocol. Data packets are kept in separate per-neighbor queues that are themselves ordered by perceived neighbor reachability. At the beginning of a slot, packet transmissions are attempted, preceded by the IEEE 802.11 RTS-CTS control handshake; the protocol visits all of the queues in a round-robin fashion. Unsuccessful transmissions cause the corresponding flow to be assigned lower priority for one-half of a slot duration, which limits the bandwidth waste incurred when transmitting on a wrong channel, or to an unreachable node. At the same time, packets are not dropped from the queue before the destination node is found unreachable during a full cycle of all channels. In this manner, the SSCH protocol is able to improve bandwidth utilization compared to other approaches.

Asynchronous Multichannel Coordination Protocol

The use of multiple channels in the *asynchronous multichannel coordination protocol* (AMCP) by Shi, Salonidis, and Knightly (2006) is guided by the goal of reducing the likelihood of starvation in CSMA-based multihop networks. In this case, the main cause of starvation is the lack of coordination between transmitters that cannot hear each other but prevent others from transmitting (even though this would not cause collisions). The AMCP protocol addresses this problem through the use of the so-called channel tables kept by each node that contain information about the scheduled availability of the data channels. In addition, each node may choose a preferred data channel for its own transmissions. When a data packet is to be transmitted, the node will check if its preferred channel is available; if not, an available channel is selected at random. The node then attempts the RTS-CTS handshake on the control channel; the RTS packet includes the information about the selected data channel. If the receiver finds it available, it responds with a so-called confirming CTS packet and immediately switches to the designated channel for data transmission. The transmitter switches to the designated channel and transmits the data packet. On successful reception, both nodes label the channel as *preferred* and switch back to the control channel. If the receiver finds that the designated channel is not available, it responds with a rejecting CTS packet that contains a list of available channels and remains on the control channel. The transmitter randomly selects another channel from those available to both transmitter and receiver and undertakes another round of control handshake.

In the AMCP protocol, coordination is accomplished as follows. A neighboring node that overhears an RTS or a

confirming CTS packet updates its channel table by labeling the designated channel unavailable for the announced duration of data transmission (including the CTS and ACK packets). No action is taken when a rejecting CTS is overheard. Starvation is avoided because this node can still use other available channels for its data transmissions. Furthermore, if the neighboring node wants to transmit data to one of the nodes that have just started their control handshake, it will defer its transmission for the entire duration of the ongoing transmission but set its contention window size to the minimum value; in this manner, it can undertake the deferred transmission as soon as possible, with a high probability of success, and thus minimize the likelihood of starvation.

MAC PROTOCOLS WITH POWER MANAGEMENT

Protocols from the power-management group try to reduce contention by controlling the transmission power on a per-packet basis. The obvious but naïve solution is to transmit RTS and CTS packets at the maximum available power so that they reach the widest possible audience. On the contrary, data and ACK packets should be transmitted at the lowest power level needed to reach their target to minimize the risk of contention. Although the risk of contention is indeed reduced but not fully eliminated, the susceptibility of data and ACK packets to noise and interference is increased. In extreme cases, this approach may result in unidirectional links—that is, one node can hear the other but the opposite is not true. These cases are much more difficult to handle.

Power-Aware Multiaccess Protocol with Signaling

Singh and Raghavendra (1998) were among the first to try to combine the MAC protocol with power-conserving features. The communication protocol itself is based on the MACA protocol (Karn 1990), augmented with a separate control and signaling channel similar in concept to the *busy tone multiple access* (BTMA) approach of Tobagi and Kleinrock (1975). In *power-aware multiaccess protocol with signaling* (PAMAS), a node that wants to transmit a packet sends the RTS packet to the designated receiver. The receiver that hears the RTS packet checks the control channel first; if no transmission is heard for a specified time t (equal to the round-trip time plus the duration of the RTS–CTS packet), it responds with the CTS packet and transmits a busy tone on the control channel. Unlike some of the algorithms described earlier, the busy tone in PAMAS is shorter: It lasts twice as long as the RTS–CTS packet. The busy tone is also sent when the node receiving a packet hears a RTS packet or detects some activity on the control channel; this prevents other potential receivers from sending their own CTS and thus prevents a potentially interfering transmission (the hidden terminal problem). On receiving the CTS packet, the sender begins the data-packet transmission. If the CTS packet is not received within the specified time-out, the sender performs a binary exponential backoff and repeats the attempt. The backoff countdown may be interrupted if an RTS re-

quest is received from another node, in which case the sender switches to reception mode according to the rules outlined above.

To conserve power, any node without packets to send goes to sleep. Moreover, if an ongoing transmission is detected in the neighborhood (through the presence of a busy tone on the control channel), all unaffected nodes should go to sleep. In the latter case, the sleep should last as long as the ongoing transmission. If the node wakes up without any packets to transmit, it goes to sleep again, but if it wakes up with a packet ready to be sent, it simply sends an RTS packet. If another transmission is in progress, the node conducts a probe over the control channel to find out how long will this transmission last. The probe protocol can be simplified considerably if the control channel is always active (Singh and Raghavendra 1998); however, this defeats the purpose for which the power control mechanism was introduced in the first place.

The PAMAS protocol is important because it shows that the medium access control mechanism can be linked with the power-conservation mechanism without affecting the end-to-end packet delay (Singh and Raghavendra 1998). Its main problem stems from the separation of data and control channels because such radios are infeasible to implement in resource-constrained sensor nodes. A further problem is the implicit assumption that switching in and out of the active state is much shorter than the average packet transmission time, which simply does not hold in most real systems.

Dynamic Power-Saving Mechanism

Jung and Vaidya (2002) have described a *dynamic power-saving mechanism* (DPSM) that optimizes the power saving mechanisms available in the IEEE 802.11 DCF (ANSI/IEEE 1999). In the DPSM scheme, time is divided into beacon intervals to which all nodes should synchronize. At the beginning of each beacon interval, all nodes must be awake for the duration of the so-called *ad hoc traffic indication message* (ATIM) window. Any node that has data to transmit announces its intention using the ATIM frame, which is subsequently acknowledged by the corresponding receiver. These transmissions are performed using the regular CSMA/CA mechanism of IEEE 802.11. Nodes that are about to receive data stay awake throughout the beacon interval, and so do the transmitting nodes that have received the proper acknowledgment. Other nodes can doze off—that is, they can switch to a low power state until the next beacon. In the original 802.11 standard (ANSI/IEEE 1999), the duration of the ATIM window is fixed, which does not give optimal results. In other words, an ATIM window that is too short means that not all nodes that have data will succeed in announcing and actually performing their transmissions, which degrades throughput. On the other hand, an ATIM window that is too long leads to higher energy consumption because all nodes must remain awake throughout this time interval, which leaves too little time for actual data transmissions and thus degrades throughput at high loads.

In DPSM, this power-saving mechanism is enhanced in several ways, all of which aim to improve power efficiency. First, ATIM windows of variable duration allow

the network to adjust to traffic conditions; in addition, each node can choose its own ATIM window size. Second, a single ATIM frame is to be used per destination node, thus reducing contention during the ATIM window. However, each data packet must contain information about the remaining number of packets to be sent, which allows the receiver to determine whether all packets were received or not. Third, a node that finishes a data transmission, either as the transmitter or the receiver, is allowed to doze off until the next beacon interval, which improves energy efficiency.

Dynamic adjustment of the ATIM window size uses several criteria: the number of packets pending transmission, the information overheard from other nodes' ATIM frames (each ATIM frame contains the information about the current contention window size of the transmitting node), the ATIM frames received while waiting for a previously announced data transmission, and the information on the number of retries for the current ATIM frame. In this manner, the DPSM scheme can be fine-tuned to improve energy efficiency without affecting throughput.

Power Control Mechanism

The power control mechanism of Jung and Vaidya (2005) uses the basic scheme described above but with the following change: The sender changes its power level from minimum to maximum during the transmission of a data packet, as shown in Figure 18. The duration of the maximum level transmission is chosen to be long enough for the nodes in the vicinity to sense the ongoing transmission and defer those of their own. In this manner, the risk of collisions is reduced (albeit not altogether eliminated), while the power consumption is reduced below that of the original IEEE 802.11 CDF.

MAC PROTOCOLS THAT USE DIRECTIONAL ANTENNAE

The protocols in the group use directional antennae to limit the spatial coverage of data transmissions and, consequently, reduce the risk of collisions. The underlying assumption is that the difference in received signal strength (i.e., the selection diversity) will allow the receiving subsystem to determine the approximate location of the correspondent (i.e., which antenna segment is to be used). The basic idea is simple: The sender sends a RTS packet in all directions and the receiver responds with an omnidirectional CTS, which informs all prospective neighbors about the forthcoming transmission. The sender transmits

the data packet using a single antenna segment: the one that is oriented toward the receiver. In this manner, it will minimize its interference with its neighbors in all other directions. This scheme is depicted in Figure 19; it was first proposed by Nasipuri et al. (2000).

The problem with this approach is that it must be coupled with power control insofar as the directional transmissions must use reduced power levels to achieve a transmission range that is equal or close to the one obtained with omnidirectional transmission. In case the same power level is used for both types of transmissions, an increase in collisions in the coverage of the directional beam will be observed.

A similar protocol is described by Ko, Shankarkuman, and Vaidya (2000), as well as by others, the main difference being the assumption that the sender knows the location of the receiver and thus can use a directional RTS instead of the omnidirectional one.

An interesting variation of the basic protocol is described by Korakis, Jakllari, and Tassiulas (2003). In this case, the RTS packet is transmitted omnidirectionally but through a one-by-one antenna segment in a circular fashion, while the CTS packet is transmitted directionally after all directions have been covered by the RTS. The RTS packet contains the information about the duration of the forthcoming transmission and the segment it covers. Hence, the nodes that hear the RTS (but are not the designated receiver) can decide whether or not to defer their transmissions. The sender listens for the CTS omnidirectionally. The data and ACK packets are sent directionally. In this manner, the potential for interference (and resulting collisions) is reduced. A simple extension of the protocol allows the nodes to record the information about their neighbors' locations, which helps avoid certain hidden terminal scenarios that result from the use of directional antennae.

Figure 19: Packet transmission using a directional antenna with four segments

Figure 18: Power profile of a packet transmission in the PCM scheme

MAC PROTOCOLS THAT USE OUT-OF-BAND SIGNALING

Ensuring collision-free data transmissions requires that the potential interfering senders are informed about pending data transmissions in a timely fashion. The protocols described in the previous section use the control handshake before the actual transmission. Although this approach does help alleviate some of the problems that may cause collision, it is unable to completely eliminate collisions. Moreover, transmitting control packets uses bandwidth, and together with backoff windows of variable size reduces the overall bandwidth utilization of the network. The protocols described in this section adopt a different approach—namely, they use a separate channel (the control channel) to convey information that prevents collisions or to conduct the actual handshake. The idea has its origins in traditional telephony systems in which a special busy tone informs the party that wants to initiate a call about another transmission in progress.

Busy Tone Multiple Access

The busy tone multiple access protocol by Tobagi and Kleinrock (1975) noted earlier is the first reported work on the busy tone approach. In BTMA, a separate control channel is used to transmit a busy tone when the node is active. The busy tone could be as simple as a pure sine wave at a predefined frequency. Any node that wants to transmit will check the control channel first. If the busy tone is present, the transmission will be deferred for some random time; if the control channel is idle, the node starts transmitting the busy tone and simultaneously starts its data transmission. In the original proposal, the transmission power of the control channel is increased to ensure that the range of the busy tone is approximately twice that of the data transmission; a later modification uses the same transmission range for both channels but mandates that the nodes that sense the data transmission in progress forward the busy tone to other nodes in their transmission range. Either way, no other node within the two-hop transmission range is allowed to transmit. This approach is simple and effective—but perhaps too effective because many of the nodes prevented from transmitting could actually engage in communications of their own without interfering with the current transmission. Bandwidth utilization tends to be poor.

Receiver-Initiated BTMA

A derivative of the basic BTMA known as *receiver-initiated BTMA* (RI-BTMA), originally described by Wu and Li (1987), combines a time-slotted approach akin to TDMA with a much simpler handshake protocol that employs a single busy tone. In this case, the prospective sender listens to the control channel until it finds a free slot—that is, the one without a busy tone. Once such a slot is found, it sends a small preamble packet on the data channel. (The time slot on both data and control channels is equal to the duration of the preamble packet.) The designated receiver responds by activating its busy tone on the control channel. On hearing this tone, the sender may

begin the data-packet transmission. Once the packet is received, the receiver turns off the busy tone.

Dual BTMA

Deng and Haas (1998) have proposed an improved version of this approach, called the *dual busy tone multiple access* (DBTMA). In this protocol, the data channel is used exclusively for data transmissions, whereas the control channel is used for the RTS-CTS handshake and for two busy tones that indicate a reception and a transmission in progress, respectively.

The DBTMA protocol operates as follows. A node that wants to transmit a packet checks the control channel for the presence of a receiving busy tone; if none is detected, the node sends the RTS packet to the receiver on the control channel. On receiving the RTS packet, the receiver checks the control channel for the presence of a transmitting busy tone, which would indicate that a transmission is already in progress in the vicinity. If none is present, the receiver responds with a CTS packet via the control channel and then activates its receiving busy tone to alert other nodes in its vicinity that it is receiving a data packet. On receiving the CTS packet, the sender activates the transmitting busy tone on the control channel and begins the data transmission on the data channel. When the data-packet transmission is finished, the sender turns off the transmitting busy tone; the receiver turns off the receiving busy tone after it has received the data packet.

The DBTMA protocol is able to achieve almost twice the value of channel utilization of the basic BTMA or some RTS- and CTS-based protocols such as MACA or MACAW, mainly because the use of two busy tones blocks only the transmissions from nodes in the vicinity of the receiver but not those in the vicinity of the sender.

The main problem with all protocols based on the busy tone approach is the need for two radios because the busy tone uses a different frequency or frequencies from the data channel. This requirement may not be simple to satisfy, in particular in conjunction with other requirements such as small physical size and limited energy source. On account of this, MAC protocols that utilize a separate control channel with busy tones have not been especially successful in practice.

MAC PROTOCOLS THAT USE POLLING

Bluetooth

Bluetooth is among the few true polling protocols used in ad hoc networks (Bluetooth SIG 2004), thus its adoption as the IEEE standard 802.15.1 (IEEE 2002). Bluetooth devices are organized in small networks known as *piconets*, with as many as 255 devices; one acts as the master and as many as seven others can be active at any given time; the remaining ones are parked. The channel time is divided into time slots of $T = 625 \mu\text{s}$, and all communications in the piconet are synchronized to this clock. Bluetooth uses a variant of the TDMA protocol in which all communications are performed under the control of the piconet master; in fact, all communications in the piconet must pass *through* the master. The master polls the slaves by sending them packets with appropriate identification; slaves can

Figure 20: TDD communication in a Bluetooth piconet

talk back to the master only when addressed and only immediately after being addressed by the master. The operation of this protocol is schematically shown in Figure 20.

Master (downlink) and slave (uplink) transmissions occur in alternative slots in a scheme known as *time-division duplexing* (TDD). The Bluetooth TDD protocol requires that an addressed slave must respond to the master's poll even when it has no data to send; a similar requirement holds for the master as well (in Figure 20, white symbols denote empty packets while gray symbols denote packets that carry data). An important consequence of the TDD protocol is that both the throughput and end-to-end delays critically depend on the polling discipline—that is, the algorithm used by the master to poll active slaves in the piconet. Several such disciplines have been proposed and analyzed in recent years; a detailed overview and analysis can be found in Mišić and Mišić (2005).

The TDD protocol is collision-free and, in theory, should be more energy-efficient than the collision-based MAC protocols, but the advantage is not so noticeable in practice. The main source of inefficiency of the protocol is the fact that even empty packets use bandwidth: They last for one slot T , whereas data packets can last for one, three, or five slots T . Furthermore, all slaves must listen to master transmissions at all times and respond when polled, even when there is no data to transmit in either direction. Special modes defined by the official Bluetooth standard allow slaves to detach temporarily from the piconet to minimize energy consumption or perform other tasks (Bluetooth SIG 2004).

SENSOR NETWORKS

Sensor networks are a class of wireless networks intended for monitoring environmental phenomena in a given physical space; such networks find increasing usage in areas as diverse as military applications, object surveillance, structural health monitoring, and agriculture and forestry, among others. Monitoring may be continuous, with a prescribed data rate that may change over time; it may also be triggered by an explicit demand from a controlling node or a specific event in the environment. Environmental phenomena to be monitored include simple physical variables such as temperature, humidity, light, pressure, pH value, and the like; however, other phenomena also can be monitored, such as the presence or absence of a specific object (say, an inventory item with a radio frequency ID

tag), or movements of persons and objects (e.g., cars). The spaces to be monitored include rooms, hallways, foyers, homes, backyards, streets, and larger buildings and structures (e.g., bridges) as well as open spaces such as fields or forests. Sensor nodes can be deployed in large numbers—from tens through hundreds to even thousands. Sensor networks are often expected to operate autonomously, with little or no human intervention, for prolonged periods of time. Sensor nodes are seldom mobile, and even when mobility is present, not all of the nodes are equipped with appropriate capabilities. Given such a diverse set of applications and requirements, it should come as no surprise that the constraints that guide the design and deployment of wireless sensor networks differ, sometimes substantially, from those that hold in wireless ad hoc networks (Sohrabi et al. 2000; Achir and Ouvry 2004). Let us now discuss those constraints in more detail.

Energy Efficiency

Probably the most important difference results from the fact that sensor nodes typically operate on limited battery power, which means that the maximization of network lifetime (and, consequently, minimization of power consumption) is *sine qua non* for sensor networks. On the contrary, power consumption is seldom the critical requirement for ad hoc networks.

The constraint of minimal energy consumption translates into two distinct yet closely related design requirements (Jones et al. 2001):

1. The communication efficiency must be maximized through the design of simple yet flexible and effective communication protocols and functions.
2. Those protocols and functions must be implemented by small chips with limited computational and memory resources. Simultaneous achievement of these objectives necessitates some kind of cross-layer protocol optimization in which the MAC layer would use the information obtained from the PHY layer to control its own operational characteristics. At the same time, optimal operation of the upper, network, and transport layers requires the knowledge of appropriate information from both the PHY and MAC layers. Again, such tight integration is not common in ad hoc networks.

An important consequence of the requirement for energy efficiency is the limited transmission range of most sensor node radio subsystems; few real devices have a transmission range of more than 100 meters (300 feet), and ranges of 10 meters (30 feet) and even less are not uncommon.

Protocol Efficiency

Regarding communication protocols, the main sources of inefficiency are packet collisions, but also overly complex handshake protocols, receiving packets destined for other nodes, and idle listening to the medium (Singh and Raghavendra 1998; Ye, Heidemann, and Estrin 2004). Actual power consumption of sensor nodes, often called *motes*, depends mostly on the radio subsystem and its operating mode. In most (but not all) cases, transmitting

uses 25 percent to 100 percent more energy than receiving; idle mode in which the radio is turned on but does not transmit or receive consumes some 10 percent to 20 percent less energy than receiving (Stemm and Katz 1997; Bhardwaj and Chandrakasan 2002). However, most savings can be made by putting the node to sleep, when power consumption drops by one to two orders of magnitude, depending on the hardware (Jung and Vaidya 2002; Van Dam and Langendoen 2003).

Use of Redundant Sensors

Because nodes are small and cheap to produce and the network lifetime needs to be maximized, it is often feasible to deploy the sensors in a given physical space in much larger numbers than necessary to obtain the desired rate of information flow. If redundant sensors are used, they can be periodically sent to sleep to minimize their duty cycle, which extends the lifetime of individual sensors and of the entire network and reduces or eliminates the need for operator intervention, thus reducing the operational cost of the network (Akan and Akyildiz 2005). The use of redundant sensors has profound implications on the design of MAC protocols, as will be seen below.

Node Specialization

Another important distinction is related to the role of individual nodes. An ad hoc network allows its nodes to choose the specific role, or roles, they would like to play—data source, destination, or intermediate router—at any given time. In most cases, a node is free to switch to a different role or roles whenever it finds it appropriate or is instructed to do so by the specific application currently executing on it. On the contrary, nodes in a sensor network have specific roles that either do not change often or never change at all. Most of the nodes act as sensing nodes, some act as intermediaries that route the traffic and (possibly) performs some administrative duties, and a small number of nodes (sometimes only a single node) act as the network sink (or sinks) toward which all the sensed data ultimately flows (Akyildiz et al. 2002). A group of sensor nodes under the control of an intermediary is sometimes referred to as a *subnetwork* or *cluster*, while the intermediary itself is known as *cluster-head*. We note that the number of intermediate levels interposed between the sensing nodes and the network sinks depends on several variables such as the size of the network, the size of the physical space that the network has to monitor, the transmission range of individual nodes, and (to some extent) the actual MAC protocol used.

Traffic Characteristics

The traffic in sensor networks is rather asymmetric because the bulk of it flows from the sensing nodes toward the network sink (this is often referred to as the *uplink* direction). The traffic in the opposite direction is generally much smaller and consists of control information and possibly queries issued by the network sink on behalf of the corresponding sensing application (Intanagonwiwat, Govindan, and Estrin 2000). Furthermore, traffic patterns in sensor networks are rather different than in ad hoc networks.

For example, temperature or humidity monitoring might require periodic or nearly periodic transmissions—in essence, synchronous traffic with low data rate—whereas object surveillance and other event-driven sensing applications exhibit low average traffic volume and random bursts with considerably higher peak rates.

Furthermore, data packets are often much smaller in sensor networks. Original data from sensing nodes typically consists of only a few data values reported by appropriate sensors. Intermediate nodes may choose to aggregate those values to improve energy efficiency and reduce bandwidth and energy consumption; data aggregation is more common in networks with a larger number of hierarchical levels. At the same time, the number of sensor nodes and their spatial density may be extremely large, depending on the size of the space to be monitored and the requirements of the sensing application.

Quality-of-Service Requirements

Maintaining prescribed delay bounds in a network of resource-constrained nodes with limited transmission range is a complex issue. Delay considerations are of crucial importance in certain classes of applications—for example, in military applications such as battlefield communications and detection and monitoring of troop movement, or in health care applications where patients in special care units must be monitored for important health variables (via ECG or EEG) because of a serious and urgent medical condition. Low delays can be achieved either by bandwidth reservation, as utilized in variations of the TDMA approach, or by some kind of admission control that will prevent network congestion, if the CSMA approach is used. At the same time, the requirement for maximum throughput is relaxed because of the following. First, the exact value of the throughput requirement is usually prescribed by the sensing application, unlike general networks where the goal is to obtain as much throughput as possible. Second, energy efficiency dictates the use of protocols that incorporate power control, which will strive to keep the nodes inactive for as long as possible (Akan and Akyildiz 2005). To obtain the desired throughput, it suffices to adjust the mean number of active nodes.

Even packet losses can be catered to in this manner because we do not care whether a given packet from a given node will reach the network sink—as long as the sink receives a sufficient number of packets from other nodes. Any packet loss can be compensated for (in the long term) by varying the mean number of active nodes. In a certain sense, fairness is not needed at the node and packet level as long as it is maintained at the cluster level (Callaway 2004). On the contrary, fairness at the node and packet level is important in ad hoc networks.

Differences from Ad Hoc Networks

The requirements outlined above lead to several important differences between sensor networks and ad hoc networks, most notably the following:

- Power efficiency and lifetime maximization are the foremost requirements for sensor networks.

- Self-organization is important in both ad hoc and sensor networks. In the former case, this is because of dynamics and node mobility, which cause frequent topology changes and makes self-organization more difficult; in the latter, this is mostly caused by sensor nodes exhausting their battery power (i.e., dying), although mobile sensors are used in some applications.
- Throughput maximization is often required in ad hoc networks but is not too common in sensor networks.
- Delay minimization is typically assigned much higher priority in sensor networks than in their ad hoc siblings.
- The use of redundant sensors allows for a certain level of fault tolerance; on the contrary, packet losses are intolerable in ad hoc networks.
- Scalability is an important issue because of the potentially large number of sensors; scalability is also important in ad hoc networks, but it is limited by the available bandwidth and the desired throughput.
- Nodes in ad hoc networks are often mobile, whereas most sensor networks have no mobile nodes.

In more than one sense, wireless ad hoc networks are a class of networks with flexible topology but without infrastructure, which should cater to all kinds of networking tasks. On the other hand, sensor networks are highly specialized networks that perform a rather restricted set of tasks under severe computational and communication restrictions.

MAC PROTOCOLS FOR WIRELESS SENSOR NETWORKS

The requirements and constraints outlined above mean that the design of wireless sensor networks and their associated protocols is a rather challenging task. The discussions that follow will present several MAC protocols for wireless sensor networks and highlight the conceptual approaches in which they attempt to address those challenges. Similar overviews can be found in Akyildiz et al. (2002) and, more recently, in Demirkol, Ersoy, and Alagöz (2006). Furthermore, an interesting overview of some of the protocols (and a detailed description of others) can be found in Sohrabi et al. (2000).

In the following, we will briefly present a couple of representative MAC protocols for sensor networks. Second, we present the recently adopted IEEE 802.15.1 and IEEE 802.15.4 standards as the industry standards for *wireless personal area networks* (WPANs) that hold great potential for *wireless sensor network* (WSN) application. We agree with the opinion expressed by Callaway (2004) that “the success of wireless sensor networks as a technology rests on the success of the standardization efforts to unify the market and avoiding the proliferation of proprietary, incompatible protocols that, although, perhaps optimal in their individual market niches, will limit the size of overall wireless sensor market.”

Adaptive Rate Control with CSMA

Woo and Culler (2001) have augmented the basic CSMA protocol with adaptive rate control to improve energy efficiency and so-called multihop fairness—that is, in

multihop scenarios, fairness can be measured as the balance between the traffic that originates in the node itself and the traffic that the node has to relay on behalf of others (route-thru traffic). Note that the traffic generated by any given node is, in fact, the route-thru traffic for all other nodes it has to pass through.

In the ideal case—a network with symmetric traffic—the knowledge about the total number of size of the network would help the node to estimate the allowed amount of its contribution. Because this information is hard or even impossible to obtain, an adaptive mechanism with a linear increase and multiplicative decrease is used to control the transmission rate of an application. The goal for any given node is to ensure fairness among all nodes whose traffic it routes. Moreover, because dropping the route-thru traffic is a waste of resources (it will have to go through that same route again or be lost), such traffic is given preference over the locally generated one. Measures are also taken to reduce the impact of the hidden node problem for pairs of nodes that are two hops away yet able to hear one another, for which Woo and Culler (2001) use the terms *child* and *grandparent nodes*.

When used in conjunction with a random delay before transmission, the adaptive rate mechanism provides an effective control mechanism without explicit control packets, in particular in scenarios where traffic loads are low, which is common in many sensor network applications.

S-MAC

The S-MAC protocol is designed for deployment in multihop WSN, where packet destinations are uniformly distributed (Ye, Heidemann, and Estrin 2004). Each device alternates between active periods, in which it communicates with other nodes, and inactive or sleep periods that ensure energy efficiency by keeping the duty cycle low. A complete cycle that includes an active and an inactive period is referred to as a *frame*. The information about the identity of the sensor node and its next scheduled sleep time is called an *activity schedule*.

The main feature of S-MAC is the self-synchronization of activity schedules for different sensor nodes, which is achieved as follows. On returning from sleep, a node listens to the medium for a specified time to check for other nodes' schedules. If a schedule is received, it is immediately adopted and followed; if not, the node chooses a schedule of its own and starts to follow it. Either way, it will start broadcasting SYNC packets with the information about the adopted schedule. However, if a node receives a different schedule at a later time, it may drop its own schedule and adopt the new one. Alternatively, it can add the new schedule to its own, which facilitates multihop communications between nodes that cannot communicate directly because of limited transmission range. A node periodically listens to SYNC broadcasts from other nodes; this lessens the risk of neighbor nodes following completely different schedules (and missing each other's active periods) and facilitates schedule reconfiguration when the network topology changes. In this manner, nodes collect information about their neighbors and build local tables of active periods of neighbors. Each node uses its table to schedule its sleep periods with the goal of being awake simultaneously

with some of its neighbors so that packet exchange can take place. In fact, *virtual clusters* are formed by the nodes that follow the same schedule; this facilitates communication among them.

During the active period, a node either listens or transmits a data packet. The listening period is organized in two phases that accommodate SYNC broadcasts and data transmissions, respectively. Packet transmission is achieved using slotted CSMA with RTS–CTS handshake. Before the node sends a SYNC or RTS packet of its own, it listens to the medium for a random period of time. After the transmission of a RTS packet, node waits for the CTS packet and then transmits the data packet. If the CTS response does not arrive during the listening period, then the node goes back to sleep and tries again in the next active period.

The delay in multihop transmissions can be extremely long if each node along the route receives the packet in one active period and transmits it in the next one. To reduce this delay, nodes in S-MAC use the so-called adaptive listening: A node that overhears the neighbor's transmission (RTS or CTS) will stay awake beyond the end of the active period. In this manner, if this node is the next destination of the packet, it can receive it immediately rather than after going through the sleep period.

To reduce transmission latency, a node that has more than one packet to send (a burst) can use only one control handshake per burst. This feature is referred to as *message passing* (Ye, Heidemann, and Estrin 2004). However, explicit acknowledgments are required after each successfully transmitted packet, which somewhat offsets the power savings obtained by spreading the cost of the handshake over all packets in the burst. If an ACK packet is not received, the sender will retry the transmission of the last packet; if the maximum number of retries is reached, the sender will abort the transmission and start over. Acknowledgments ensure reliable transmission but also inform other nodes about the transmission in progress and thus help avoid the hidden terminal problem. In other words, both data and ACK packets have a duration field that specifies the total transmission time for the burst, including the ACK packets. Therefore, nodes that hear either a data packet or an ACK packet from an ongoing burst transmission may go to sleep until its scheduled finish time.

Although simple and efficient, S-MAC suffers from scalability problems. As the size of the network increases, it becomes increasingly difficult for a node to maintain a coordinated schedule, and the power consumption of relaying nodes—which have to receive and transmit packets—increases. As a result, energy efficiency deteriorates. Decreasing the duty cycle may counter this trend, but it increases the delays and reduces the throughput.

Time-Out MAC

The main drawback of the S-MAC is the fixed duty cycle—that is, the ratio of the active period to the entire frame time, which does not depend on the traffic in the network. To reduce the power consumption even more, active periods should be as short as possible under the given traffic pattern. This is the main concept of the *time-out MAC* (T-MAC) proposed by Van Dam and Langendoen (2003).

The T-MAC borrows the concept of distributed synchronization from the S-MAC, except that nodes that hear a schedule different from their own must follow both (this is not mandatory in S-MAC). This provision ensures that neighboring nodes will always be able to communicate.

T-MAC nodes can optionally go to sleep when they hear an ongoing transmission of which they are not a party. Although this forced sleep (which is mandatory in S-MAC) may save energy, it also leads to increased collision overhead and reduced throughput (Van Dam and Langendoen 2003).

In T-MAC, a node keeps listening and (perhaps) transmitting as long as it is active. It will switch to sleep if no activation event has occurred for a specified time TA . Activation events include activity on the medium, including end of own transmission or acknowledgment, and the firing of an activation timer (which brings a sleeping node back to the active state). The time-out value TA is chosen to ensure that the node does not miss any communication directed to it. Nodes that have data packets must attempt transmission as soon as their active period starts; other nodes in its neighborhood will be awake and, hopefully, able to receive the data. A potential sender listens to the medium for a random time within a fixed contention interval and then undertakes the RTS–CTS handshake.

As noted earlier, many sensor networks exhibit asymmetric traffic patterns: The bulk of the traffic is directed toward the network sink. In this case, it is possible that some transmissions will be delayed until the next active period simply because one of the relaying nodes was unaware of it and went to sleep (the early sleeping problem) as shown in Figure 21. To overcome this problem, the node that overhears a CTS packet destined for another node can send a *future request to send* (FRTS) packet to inform the future destination node about the forthcoming data transmission. The FRTS packet contains the duration of the transmission copied from the CTS packet; the destination node can then stay awake for that long. This mechanism, shown in Figure 22, reduces the delay and increases the overall throughput of the network.

Another possible problem in multihop relaying is that an intermediate node that has a nearly full buffer with data to forward receives the RTS packet announcing a forthcoming data transmission from another sender. Accepting that data increases the risk of buffer overflow and data loss; in addition, it may increase the delay because of the early sleeping problem. The T-MAC protocol allows such a node to give priority to its own transmission by sending a RTS packet to the proper destination rather

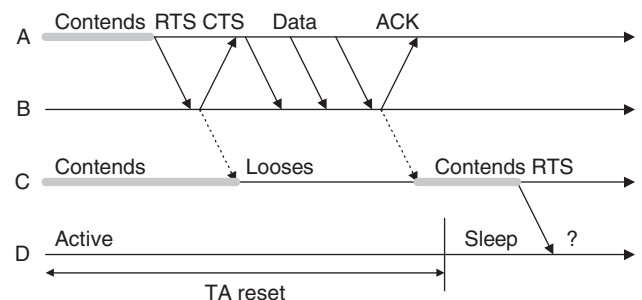

Figure 21: Early sleeping problem in multihop communication

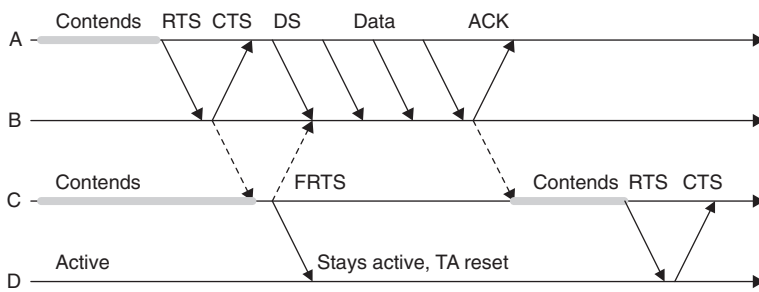

Figure 22: The use of FRTS packet avoids early sleeping

Figure 23: Time slot organization in TRAMA

that responding with the CTS packet as usual. In fact, such a node takes over the medium, which it has effectively won anyway, only for a different purpose.

Although this technique, known as *full-buffer priority*, can offer substantial improvement in performance, it may be risky to use under heavy loads: If too many nodes start taking over the medium, the risk of collisions rapidly increases. To avoid such situations, the node is allowed to use full-buffer priority only if the number of times it has lost contention exceeds the predefined threshold.

Traffic-Adaptive Medium Access

Although the T-MAC protocol is able to offer considerable power savings compared to S-MAC under variable workloads, it suffers from similar problems related to scalability, especially under heavy loads. A possible solution to keep the energy efficiency under control is to reduce the timeout value, but this increases delays and impairs the ability to react to changing network conditions. The *traffic-adaptive medium access* (TRAMA) protocol proposed by Rajendran, Obraczka, and Garcia-Luna-Aceves (2006) attempts to overcome this problem through a traffic-adaptive scheme that selects receivers according to announced transmitter schedules. It is based on an earlier protocol known as *node-activation multiple access* (Bao and Garcia-Luna-Aceves 2001) has employed a similar approach but without concern for energy efficiency.

TRAMA assumes a single, time-slotted channel for both data and control transmissions. Time is divided into periods of random access, interleaved with periods of scheduled access, as shown in Figure 23.

Three subprotocols are used to exchange neighbor information (*neighbor protocol*, or NP), exchange schedule information (schedule exchange protocol), and elect the transmitters and receivers for the current time slot (adaptive election algorithm). The network starts in random access period wherein each node transmits basic signaling information in a randomly selected slot. This period essentially serves to construct and subsequently maintain the information about the node's neighbors. Although collisions of signaling packets are possible, the duration

of the random access period is chosen to guarantee consistent neighbor information with a high degree of confidence.

Each node calculates its schedule interval based on the traffic pattern of the application and the neighbor information obtained in the NP phase. In addition, it calculates the number of slots in the subsequent schedule interval for which it has the highest priority among its two-hop neighbors (the winning slots). This information, together with the designated receivers for those slots (i.e., the packets to be transmitted therein), is announced through schedule packets. Priority is determined according to node identity and the time slot in question; ideally, this process assigns unique (and globally known) priorities to each node and time slot combination. A node may give up its slot if there are no data packets to transmit; such vacant slots can be used by other nodes in the neighborhood. Some of its winning slots will go unused if the number of such slots exceeds the number necessary to transmit all the data in that node's queue. The ChangeOver slot denotes the slot after which all winning slots are unused; it is used for announcing the next schedule, and all of the nodes must listen to it. A node that has no data to send and has not been designated as the receiver may switch to low-power mode until the next ChangeOver slot.

Although the scheduling mechanism used in TRAMA ensures collision-free data transmissions and allows for longer sleep times than in other protocols such as S-MAC, some inefficiency is caused by the fixed size of the transmission slots, which imposes a lower limit on the duty cycle. Another problem is that the priority calculations must be repeated for each slot in every scheduled access period, which may cause problems in a network implemented with resource-constrained nodes.

Other MAC Protocols for Sensor Networks

In the following, we will briefly mention several other protocols for wireless sensor networks, both those that focus entirely on MAC layer issues and those that include issues related to other layers as well. The reader should note that a several subsequent chapters are devoted to

issues of broadcasting, routing, data gathering, and localization in sensor networks.

Low Energy Adaptive Clustering Hierarchy

Heinzelman, Chandrakasan, and Balakrishnan (2000) have attempted to minimize energy consumption in the scenario in which the sensor networks consists of several identical, resource-constrained nodes that generate unidirectional traffic sent to a single network sink. Although this protocol, known as *low energy adaptive clustering hierarchy* (LEACH), focuses mostly on routing issues, it does integrate elements from both network and MAC layer, which is why a brief overview is included here.

The main idea of the LEACH algorithm is that the sensors should autonomously organize themselves into clusters, with one node acting as the cluster-head. Sensors elect themselves to be the cluster-heads with a certain probability, which depends on the remaining energy of the sensor and the number of sensors in the entire network. Becoming the cluster-head is a unilateral decision and no negotiation is involved. To balance the power consumption, the role of the cluster-head is randomly rotated among the sensors in the cluster.

Once elected, the cluster-head advertises its presence. All sensor nodes must listen to the advertisements. They decide which cluster they will join and inform the corresponding cluster-head. All transmissions so far use CSMA. When the cluster-head gathers sufficient knowledge about the sensors in its cluster, it creates a TDMA transmission schedule and broadcasts it. (The original proposal assumes that CDMA coding is used for intracluster communication so that collisions can be avoided.) Once a sensor knows its cluster and its transmission schedule, it may go to sleep until the time comes for its transmission, thus conserving the least amount of power.

When the cluster-head receives the data from all the sensors in the cluster, it aggregates it and sends it to the network sink. A new round of clustering then follows.

Ideally, the LEACH algorithm should result in energy levels of individual sensors being used up at about the same rate. Of course, the cluster-head must remain active throughout the entire cycle, but the rotation of the cluster-head role should ensure that the load is evenly balanced among all nodes.

Wave Scheduling

Wave scheduling, originally proposed by Trigoni et al. (2004), is an example of an integrated protocol that spans the MAC, network, and even portions of the transport layer of the traditional networking protocol stack (Stallings 2002). It partitions the network into cells such that the nodes in a cell are assumed to be able to communicate only with the nodes in their own cell and its immediate neighbors. In fact, the assumption is that the cells are near rectangular, although this is not necessary for the proper functioning of the algorithm.

Transmissions are then scheduled utilizing a sequence of activations of edges that connect two cells. Each activation period includes a contention-based period followed by a contention-free period. In the contention period, the GAF scheduling protocol (Xu, Heidemann, and Estrin 2001) is run locally in each cell: The nodes attempt to

determine whether the current leader has sufficient energy to continue its leadership role. If this is not the case, then a new leader is elected and messages queued for delivery are handed over by the previous leader, together with intercell routing information. The remaining nodes send the sensed data to the leader. Ordinary nodes can then go to sleep until the next activation period. In the contention-free period, accumulated messages are transferred from one cell leader to the next one. A special message informs the receiver if there are no messages to deliver, in which case both leaders can go to sleep to conserve energy.

Two distinct wave schedules are defined. In the *simple wave* schedule, messages are coordinated in east–west and north–south directions. This allows simultaneous transmissions from the leaders when the distance between them exceeds the transmission range. North–south and east–west schedules occur in interleaved fashion. In the *pipelined wave*, the graph obtained by the cell-to-cell edges is partitioned into a collection of maximal independent sets that can then be activated simultaneously without interference. Both wave schedules avoid interference, and they can be tuned to achieve minimum energy or minimum delay routing.

Stationary MAC and Startup

The *stationary MAC and startup* (SMACS) procedure, originally proposed by Sohrabi et al. (2000), deals with the creation of a suitable TDMA-like schedule without a centralized authority. In SMACS, neighbor discovery and channel assignment phases are lumped together, and channels for node-to-node communication are assigned immediately after the two nodes involved learn about each other's existence. By the time all nodes find out about all of their neighbors, an operational network with a flat topology is formed. *Channels*, in the SMACS terminology, are in fact time slots within a superframe of sufficient duration. To reduce contention, it is advisable to assign different frequencies to different channels whenever possible.

Berkeley MAC

A rather different approach was proposed by Polastre, Hill, and Culler (2004). Instead of trying to optimize the behavior of the MAC protocol, the *Berkeley MAC* (B-MAC) protocol optimizes the low-power listening and clear channel sensing on a popular Mica2 hardware (Hill et al. 2000). Other medium access mechanisms that use these primitives can then be implemented on top of the B-MAC platform.

Zebra MAC

The *zebra MAC* or Z-MAC (Rhee et al. 2005) combines the strengths of the CSMA and TDMA approaches. A node can transmit in any time slot after successful carrier sensing, as in CSMA, but the designated owners of that particular slot take precedence. This concept reduces the risk of collision while still allowing other nodes to transmit in that slot. In addition, lightweight synchronization schemes are utilized to provide the network with some resilience to topology changes and control information loss. However, the ZMAC protocol does not consider the situation in

which individual nodes go to sleep, which severely limits its usability in several sensing applications.

IEEE 802.15.4

The recent IEEE 802.15.4 standard (IEEE 2003b) is not specifically intended for use in wireless sensor networks—it was originally designed as a *low data rate WPAN* (LR-WPAN)—but its simplicity and low data rate make it an attractive choice for sensing applications as well (Callaway 2004). The IEEE 802.15.4 protocol is a full-function MAC and PHY protocol that requires other layers above it to function properly, in contrast with most other proposals, which simplify several layers into a single, integrated one.

An IEEE 802.15.4 network can operate in two modes: (1) the beacon-enabled, slotted CSMA/CA mode in which a dedicated coordinator must be present; and (2) beaconless, unslotted CSMA/CA similar to the 802.11 DCF in its basic form (without the RTS-CTS handshake). In the former case, the interval between two successive beacon frames is split between an active and inactive period, which allows the entire network to conserve energy by going to sleep. Also, a portion of the active part of the super-frame can be reserved for scheduled access, which is allocated on request. However, requests to allocate such time must be made through packets that undergo contention. The performance of IEEE 802.15.4 networks at the MAC level is not fully explored yet, especially their suitability for low-power applications, although some results have recently been reported (Mišić, Shafi, and Mišić 2006).

CONCLUSION

As the discussion above shows, the area of MAC protocols for ad hoc and sensor networks does not suffer from any shortage of research results. Nonetheless, there are still many open issues that need to be addressed, mainly in the domain of sensor networks.

First, the selection of the actual protocol is still largely unsolved, even though most proposals use some variant of contention-based access derived from the ubiquitous CSMA approach. In addition, the problems of hidden and exposed terminals still plague most, if not all, of the proposed protocols.

Second, the simultaneous minimization of energy consumption and optimization of different performance metrics of the MAC protocol requires more research. Although some proposals do assume a specific structure of the sensor field and try to find the optimum solution for that particular case, more generic solutions are needed.

Third, synchronization problems are also difficult, in particular when sensor nodes sleep for prolonged intervals and wake up only to find that their clock has drifted away from that of the nodes that are active. Although several algorithms exist that tackle this problem, solutions that would be generic enough to fit most sensing applications have yet to be found.

From the practical perspective, we can expect further reductions in the physical size and consumption of sensor devices. Advances in integrated circuit technology will allow more complex protocols to be implemented. However, fundamental problems related to transmission range and power will still remain. In particular, severe

resource constraints mean that tight integration and cross-layer design that encompasses the functionality of PHY, MAC, routing, and (possibly) data aggregation layers will be a practical necessity.

These and many other questions will most likely be answered with further applications of wireless sensor devices.

GLOSSARY

Backoff: Random delay introduced after a node or device that wants to transmit data has detected that the medium is not idle. Often used synonymously with binary exponential backoff.

Bandwidth Reservation: A procedure through which a portion of bandwidth is reserved for exclusive use by a link (i.e., for the transmission from one node to another) before the actual transmission takes place.

Beacon: A special packet transmitted periodically by the network coordinator in order to facilitate synchronization of other nodes and devices in the network.

Binary Exponential Backoff: Backoff procedure in which the range to choose the actual backoff duration from doubles after every unsuccessful clear channel assessment (in some protocols) or attempt to transmit data (in others).

Burst: A sequence of packets transmitted in short succession, often generated by segmenting a longer packet from a higher protocol layer.

Channel Hopping: Switching through available channels (in most cases, different frequencies in the designated radio frequency band) in a defined, often pseudorandom manner, with the goal of reducing the impact of interference and noise.

Clear Channel Assessment or Clear Channel Sensing: Listening to the channel before transmission to detect whether the medium is idle (i.e., used by another node or device).

Clear-to-Send (CTS): Control packet sent by the designated data receiver to indicate its readiness to receive the data transmission from the potential transmitter. Usually sent in response to the RTS packet sent by the potential transmitter.

Cluster: Group of nodes or devices that work together under the control of a central controller or coordinator referred to as a *cluster-head*. Commonly used for sensor networks.

Collision: Situation when two or more packet transmissions overlap in time and cannot be successfully received.

Contention: Situation in which two or more nodes or devices compete for medium access.

Coordinator: Node in the network that has special responsibilities in terms of monitoring or managing network operation.

Distributed Coordinator Function (DCF): One operational mode in an IEEE 802.11 compliant network in which contention arbitration is performed without a central controller or coordinator.

Duty Cycle: Ratio of the period in which a node is active to the period in which the node is inactive (or sometimes to the sum of active and inactive period durations).

Exposed Terminal: Node or device whose transmission may prevent a potential transmitter from sending the data even though there would be no collision at the receiver.

Fairness: Ability of the network to provide sufficient (and possibly comparable) level of service to all of its nodes.

Frame: Periodic time unit containing one or more packet transmissions and other activities by participants in a communications link; sometimes grouped to form a superframe and sometimes used to designate a packet or, more precisely, any data unit defined by a particular protocol.

Handshake: Exchange of control signals in order to make proper arrangement for subsequent data exchange.

Hidden Terminal: Node or device that is beyond the reach of the transmitter node, but whose transmissions can reach the receiving node and thus cause collision.

Interframe Spacing (IFS): Prescribed time intervals between specific transmissions in an IEEE 802.11-compliant network. Several different IFS intervals exist in the 802.11 standard.

Multihop: Communication between two nodes or devices through one or more intermediary nodes.

Out-of-Band: Separate channel or, in general, any mechanism distinctly different from the regular data channel; often used for the exchange of control information.

Piggybacking: Adding a small amount of extra information to a packet that has a well-defined purpose (e.g., data or control).

Point Coordinator Function (PCF): One operational mode in an IEEE 802.11-compliant network in which one of the nodes acts as a central controller or coordinator.

Polling: Procedure whereby a coordinator node queries other nodes in the network it controls to find out the amount of data they want to transmit and thus allocate bandwidth for those transmissions.

Request-to-Send (RTS): Control packet through which a node that wants to send data informs the designated receiver (and other nodes within its transmission range) about the intended data transmission. The receiver should respond with a CTS packet.

Round-Trip Time: Time interval from the beginning of a data packet transmission to the end of the subsequent acknowledgment packet.

Scalability: Ability of the network to operate without significant changes in performance in a wide range of network sizes.

Scheduling: General procedure of allocating resources (usually time) to different links (and corresponding nodes or devices). Also used to designate the mechanism whereby allocation is performed according to some predefined criteria, including but not limited to the volume and other characteristics of traffic.

Self-Healing: Ability of the network to operate when some of its nodes suddenly cease to function.

Signaling: Generic label for communication wherein only control information is exchanged (as opposed to data transmission).

Single-Hop: Direct communication between two nodes or devices without an intermediary.

Starvation: Situation in which a node has data to transmit but cannot gain access to the medium.

Superframe: Periodic time interval (sometimes referred to as a *cycle*) that contains several smaller units, often designated as *slots* or *slices*.

INTRODUCTION

Wireless communication and networking technology is rapidly developing and evolving. In general, a wireless network can be an infrastructured or infrastructure-less (ad hoc) network. In an infrastructured wireless network, fixed and wired gateways are used to connect mobile users. In ad hoc networks, all nodes are mobile and can be connected dynamically in an arbitrary manner. All nodes of these networks can act as routers and take part in discovery and maintenance of routes to other nodes in the network. This improves network flexibility and lowers the cost of establishing wireless networks. Mobile ad hoc networks (MANETs) and wireless sensor networks (WSNs) are two prominent classes of ad hoc networks. MANETs exhibit high mobility patterns, whereas WSNs suffer from limited and unreplenishable energy sources. A WSN is composed of a large number of sensor nodes that are densely deployed either inside the phenomenon or very close to it (Akyildiz et al. 2002). The position of the nodes need not be engineered or predetermined; hence, random deployment in inaccessible areas is possible. Applications involving MANETs and WSNs are of a wide variety, including emergency response information, energy management, medical monitoring, logistics and inventory management, battlefield management, home security, machine failure diagnosis, and chemical or biological detection (Akyildiz et al. 2002).

As a result of the mobility characteristic of MANETs, the topology of the network is continuously changing. Moreover, the link weight and capacity are not stable because of many parameters such as noise, fading, power, and interference. On the other hand, the traditional wired networks have a topology that rarely changes and has stable bandwidth and low error rates. Hence, routing in wireless environments is a challenging

problem that has motivated many researchers to develop both general-purpose and problem-specific routing protocols (Royer and Toh 1999). Overall, a routing scheme for MANETs and WSNs can fall within many categories, as depicted in Figure 1(a). Note that the categories in the figure overlap one another; a set of protocols can also be divided into different categories. Another look at the classes of protocols in Figure 1(a) would result in another classification with respect to WSNs—as shown in Figure 1(b), for example.

The rest of this chapter is organized as follows. In the following section, the routing challenges in both MANETs and WSNs are discussed in detail. Next, we present a detailed classification of routing protocols in MANETs, followed by another detailed classification of routing protocols in WSNs. The final section outlines the future challenges of routing in mobile ad hoc and sensor networks.

ROUTING CHALLENGES IN MOBILE AD HOC AND SENSOR NETWORKS

Several technical challenges face the design of efficient routing protocols in MANETs. Many of these challenges are applicable to both MANETs and WSNs, especially those related to the constantly changing network topology due to node mobility in MANETs and node failure in WSNs, the limited bandwidth of a shared wireless medium, and the limited power capacity. However, there are some challenges that are specific to either MANETs or WSNs (see Akyildiz et al. [2002] for a list of differences between MANETs and WSNs). Therefore, some the routing protocols surveyed in this chapter apply to general ad hoc networks, and others are specific either to MANETs or to WSNs. The routing protocols attempt to overcome various difficulties that prevent the wide deployment of

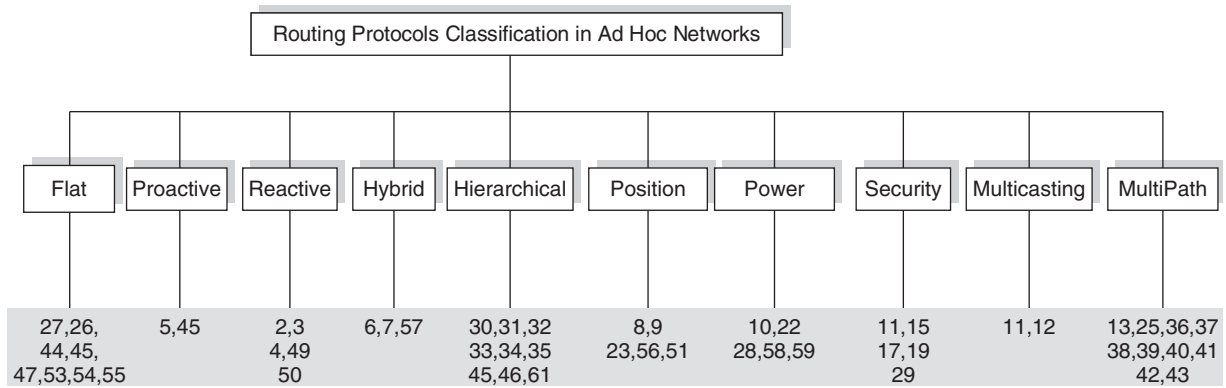

Figure 1(a): Routing protocols in MANETs and WSNs

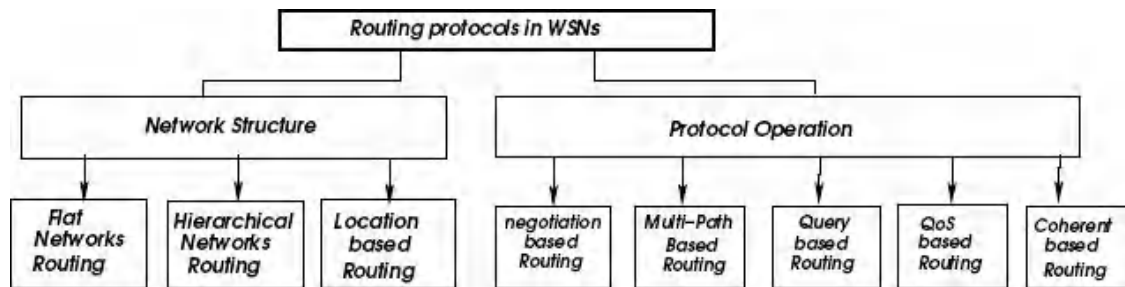

Figure 1(b): Routing protocols in WSNs—Another perspective (Al-Karaki and Kamal 2004)

MANETs and WSNs. These difficulties are a result of the following challenges:

1. *Challenges due to the dynamic topology:* The issue of mobility does not exist in fixed networks. Even in infrastructured wireless networks, the mobile nodes move from the domain of one access point to the domain of another access point. In MANETs, there is a high possibility that the topology may vary at a fast rate. The complications imposed by mobility in MANETs may severely degrade the network quality. The frequent route breakage is a natural consequence of mobility, which complicates routing. Such topological dynamics are further complicated by the natural grouping behavior in a mobile user's movement, which leads to frequent network partitioning. Network partitioning poses significant challenges to the design of routing protocols and complicates connection establishment at large. The topology in WSNs may vary as a result of node death; thus, connectivity will vary as well. That is, the malfunctioning of a few nodes can cause significant topological changes and might require rerouting of packets and reorganization of the whole network.
2. *Challenges due to the scarce resources:* The wireless spectrum is a limited resource that must be utilized efficiently. In addition, the wireless medium is a shared medium in which signal attenuation, interference, multipath propagation effects (e.g., fading), and the unguided nature of the transmitted wave all contribute to wasting the bandwidth resource. Effective management of this resource is a key factor in routing in both MANETs and WSNs.
3. *Challenges due to the absence of communication infrastructure:* Standard networks use an infrastructure. In MANETs and WSNs, there is no preexisting infrastructure or default router; every mobile node should be able to act as a router and forward packets to other nodes. Therefore, a routing protocol must consider the self-creating and self-organizing features of MANETs.
4. *Challenges due to power limitations:* The nodes in an ad hoc wireless network are typically powered by batteries with a limited energy supply. Solutions that reduce power consumption will often be favored, all other factors being equal. An important and challenging issue in ad hoc wireless networks is how to conserve energy, maximizing the lifetime of nodes and thus of the network itself. Because routing is an essential function in these networks, developing power-aware routing protocols for ad hoc wireless networks has been an intensive research area in recent years. Mobile nodes need to use their battery-limited power supply in a manner that prolongs the lifetime of the battery. If the battery power is used blindly, mobile nodes or sensor nodes will fail quickly, and this affects the network availability and functionality. Power-aware routing schemes, therefore, are designed to provide solutions for this problem.
5. *Challenges due to heterogeneous nodes and networks:* Mobile nodes can be heterogeneous, thus enabling an assortment of different types of links to be part of the same ad hoc network. MANETs are typically heterogeneous networks with various types of mobile nodes. The same issue arises when sensor nodes are equipped with batteries that have variable capabilities. Dealing with node heterogeneity is a key factor for the successful operation of routing protocols for heterogeneous MANETs.

6. *Challenges due to link quality:* The problem of link quality is particularly significant in MANETs and WSNs. The essential effect on MANETs is that the link quality can become extremely variable, often in a random manner. Although some parts of this effect can be predicted because variations in link quality impact packet delivery and trigger error-recovery procedures, many parameters such as bandwidth availability, latency, reliability, and jitter are affected. As a result, the link becomes unreliable, and this affects routing protocols.
7. *Challenges due to other layers:* Because of the direct coupling between the physical layer and the upper layers, the traditional protocol stack is not sufficient for wireless networks. Cross-layer design methodology, in which the information is exchanged between different protocol layers dynamically, is an active research area to improve wireless network performance. In a wireless network, the physical layer, media access control (MAC) layer, and routing layer all contend for the network resource. The physical layer affects MAC and routing decisions with its transmission power and rate.
8. *Challenges due to lack of centralized control:* In MANETs and WSNs, distributed algorithms are preferable because of the lack of a central entity.
9. *Transmission media:* In a multihop ad hoc network, communicating nodes are linked by a wireless medium. Each node has a limited transmission range; hence, routing is multihop in general. This imposes new requirements of node roles and the necessity of node cooperation. In a multihop ad hoc sensor network, each node plays the dual role of data originator and data router.

All of these challenges apply to both MANETs and WSNs. Certain challenges are particular to WSNs—for example, energy, computation, and communication resources. The wireless sensor node can be equipped with a limited power source that can be used to perform computations and transmit information. As such, WSN shows a strong dependence on battery lifetime. Some sensor nodes may fail or be blocked because of a lack of power, physical damage, or environmental interference. The failure of sensor nodes should not affect the overall task of the sensor network. Hence, energy-conserving forms of communication and computation are essential. Furthermore, sensors have limited computing power and therefore may not be able to run sophisticated routing protocols. The number of sensor nodes deployed in studying a phenomenon may be in the order of hundreds or thousands; depending on the application, the number of nodes can be even greater. New schemes must be able to work with this many nodes. A sensor node made up of many hardware components should be smaller than a cubic centimeter, consume extremely low power, operate unattended, operate in high volumetric densities, have low production cost, and adapt to the environment.

In the next two sections, we review the efforts that have been exerted in the area of routing in both MANETs and WSNs—in particular, fostering new routing attempts. These efforts attempt to overcome, or at least circumvent,

the aforementioned challenges to provide possible solutions to the routing problems in these networks.

ROUTING PROTOCOLS IN MOBILE AD HOC NETWORKS

This section presents a survey of the recent advances in routing protocols in MANETs. In fact, the focus of the routing protocols in MANETs spans a wide variety of topics. In particular, quality of service (QoS), power efficiency, and security mechanisms are some of the important constraints in ad hoc networks. At times, many parameters are integrated together to guarantee optimum performance with minimum overhead. It is worth noting that several studies address the routing issue in ad hoc networks along certain dimensions (Wang et al. 2000; Chaudhry et al. 2005; Higaki and Umeshima 2004; Lee et al. 2005; Wang and Olariu 2004; Ducatelle, Gianni, and Maria 2005; Nanda and Gray 2004; Lu and Feng 2005; Subramanian et al. 2004; Mao et al. 2003; Guven et al. 2005; Hong, Xu, and Gerla 2002; Hollick et al. 2004). This chapter aims to modernize and encapsulate the previous studies in a comprehensive manner. Many routing protocols have been proposed in recent years for MANETs. Traditionally, these protocols have been classified as being on-demand or table-driven-based routing protocols. Many of these protocols—for example, dynamic source routing (DSR; Johnson and Maltz 1996) and ad hoc on demand vector (AODV; Perkins, Royer, and Das 1999)—commonly use minimum hop counts as metric to find routes, operating under the assumption that a link that is good for the route discovery process is still good for data packets, and that the link quality is either good or bad. In De Couto et al. (2002), experimental evidence showed that using minimum hop count as a metric often leads to less capacity than the existing best paths, because the link quality is spread out, some links are asymmetric, and link quality varies over time. Additionally, many of the proposed protocols are dependent on either the distance vector or link-state routing algorithms. However, some protocols opt to minimize processing overhead, topology maintenance, and loop prevention.

Flat Routing Protocols

In flat networks, all nodes play the same role. In flat routing, the next hop that a mobile node will take to the destination is a physical next hop of this node. In Draves, Padhye, and Zill (2004a), multi-radio link-quality source routing (MR-LQSR) routing protocol for multihop wireless network is proposed. In this protocol, most of the nodes equipped with multiple radios are either stationary or minimally mobile. MR-LQSR is a combination of the LQSR protocol (Draves, Padhye, and Zill 2004b) and a routing metric weighted cumulative expected transmission time (WCETT). The weight is used to select the radio that has the best transmission time among the available links.

However, flat routing will cause performance degradation in large ad hoc networks for several reasons. First, the route hop count will be higher in a large-scale network, causing more route breakage and end-to-end

delay. Second, the overhead introduced by the routing protocol can consume more network capacity. Third, the routing information about remote nodes can be inaccurate as a result of the long transmission time.

Reactive or On-Demand Routing Protocols

On-demand routing protocols typically search for a route only when needed. They normally operate on flat as well as hierarchical architectures. Moreover, they are widely used in multipath routing protocols because they can recover from route changes more efficiently than other protocols. The multipath source routing (MSR; Wang et al. 2000) protocol provides an example of such protocols. MSR is an extension of DSR in which all of the discovered paths are stored in a route cache with a unique route index in a process called *path finding*. In this algorithm, the routing loops can be easily detected and eliminated. In MSR, the route is determined by the source and intermediate nodes only forward the packets (see Figure 2).

As a result, the computation complexity is limited in the source nodes. It has been found that the throughput and end-to-end delay are improved using the MSR instead of DSR. However, the main drawback of this protocol is the processing overload of originating the packets.

Another on-demand protocol is the ad hoc on-demand multipath distance vector (AOMDV; Chaudhry et al. 2005) protocol, which uses the traditional single path routing protocol—ad hoc on-demand distance vector

(AODV) protocol—to generate multiple paths. AOMDV reduces the delay up to 20 percent and also reduces the frequencies of route discovery. AODV determines the path of the route only when the source node needs to send data. The mobile intermediate nodes keep track of neighbors by sending hello messages and determine the validity of routes by setting timers. When the link is broken, an error message is sent to the source node to delete the broken link entry. The AODV mechanism is shown in Figure 3.

Another on-demand routing protocol is multiple route AODV (MRAODV; Higaki and Umeshima 2004). MRAODV confronts the mobility nature of ad hoc networks by finding multipaths to send data between a pair of source/destination nodes. In MRAODV, separated reverse path fragments are connected to achieve additional routes. According to simulation results, more additional routes are detected in this protocol than in other protocols. Figure 3 shows the operation of the protocol in a high-level perspective in which the source node can reach the destination node using multiple paths. Note that, when a path is broken, an error message is used to notify the sender of route invalidity.

Proactive Routing Protocols

This set of protocols keeps track of route updates between different nodes at all times. It also monitors the changes in network topology and thus guarantees that the destination node will be reachable. Proactive protocols distinguish themselves from the reactive ones with

Figure 2: The MSR routing protocol operation

Figure 3: AODV routing mechanism

the ability to recover from broken routes in a short time by always keeping an image of network topology. However, the proactive protocols may incur high overhead in order to maintain up-to-date images of the network topology and may also result in latency in receiving valid routing information.

The traditional destination sequenced distance vector (DSDV) is an example of such protocols, in which every routing node stores a routing table to all destinations. Nodes periodically update the routing tables by sending either the full routing table or simply the new changes in the network topology. To improve the performance of the DSDV, a new routing protocol that utilizes multiple channels was proposed in Lee et al. (2005). A DSDV with multi-channels (DSDV-MC) uses multiple channels to obtain the use of alternative paths and thus increase capacity and recover from errors immediately. Moreover, the protocol uses one channel for control messages and another channel for user data to avoid the inefficiency of bandwidth utilization from routing table update messages. Results have shown that DSDV-MC enhances the traditional DSDV by lowering the packet drop rate. To avoid inefficiencies from periodic updates in the proactive routing protocol, the proposed scheme divides the network layer into control and data planes. Nodes send routing updates using the control channel and user packets using the data channel. Simulation results indicate that DSDV-MC exploits multiple channels to improve network capacity.

Hybrid Routing Protocols

This type of protocol incorporates the functionality of both the on-demand routing algorithms and the proactive ones. Hence, the performance of the protocol is expected to outperform that of the two previously mentioned protocol types. The traditional zone routing protocol (ZRP) is an example of such protocols. ZRP is locally proactive

and globally reactive; each node in the architecture behaves as both a cluster head and a member of other clusters at the same time. The goal of ZRP is to minimize the sum of the proactive and reactive control overhead. The key idea of ZRP is that each node proactively advertises its link state over a fixed number of hops, called the zone radius. The nodes on the boundary of the routing zone are called *peripheral nodes* and play an important role in the reactive zone-based route discovery. One of the drawbacks of the ZRP algorithm is that more memory is required because of the hierarchical structure of the algorithm, which does not exist in the proactive or on-demand routing algorithms. An enhancement over ZRP is the two-zone routing protocol (TZRP; Wang and Olariu 2004), a hybrid routing protocol in which a single zone serves a dual purpose. Specifically, TZRP aims to decouple the protocol's ability to adapt to traffic characteristics from its ability to adapt to mobility. To do that, each node maintains two zones: a crisp zone and a fuzzy zone. By adjusting the sizes of these two zones independently, a lower total routing control overhead can be achieved.

Another hybrid routing algorithm is an agent for hybrid multipath routing in mobile ad hoc networks (AntHocNet; Ducatelle, Gianni, and Maria 2005), in which the route setup of this scheme is performed by an on-demand algorithm and the route exploration is done via proactive scheme. This protocol is built on top of an ant colony optimization (ACO) framework. It has been observed that ants can converge to the shortest path between the nest and the food source, thereby eliminating all other paths. This was the main idea of AntHocNet. To apply the concept of ACO, each node in MANET generates ants to the desired destination. While the ants are moving, they collect information about the path such as the number of hops, connection quality, and round-trip time. When it reaches the destination food source, it returns back to the source and modifies the routing table of the intermediate nodes. The routing tables at each node contain all possible paths to the desired destination with a value that indicates the quality of the link. This value is modified periodically by the ants on their way back to the nest. The modified values are used to select multiple paths for both ants and data. Following this approach, path quality value is modified periodically, the routing decision is done locally, and data can be sent via several paths to enable load balancing. However, drawbacks include relatively large amounts of overhead as well as reduced adaptability to the network situation.

Virtual backbone routing (VBR) is proposed in Liang and Haas (2006). It combines both local proactive and global reactive routing over a variable-sized zone hierarchy. It is a scalable routing protocol that utilizes the idea of selective representation of topology details, in which each node maintains routing information about close links only, and the initiated route queries need not reach the far nodes. The VB is constructed from nodes selected dynamically during the network lifetime and is refreshed through a distributed database coverage heuristic (DDCH). Each node within the VB serves as a database that is queried by source nodes to get information about all links within the database zone. DDCH is a distributed algorithm to generate VB. Initially, nodes are not connected to any database; they are in the *panic state*. Each node that

has the maximum dependency number within its zone (i.e., the maximum number of panic nodes, including the node itself) joins the current VB. VBR construct routes based on the least number of hops criteria.

Geographic Position-Assisted Protocols

This set of routing protocols uses the position information to select the best route that can minimize power, overhead, and latency (Mauve, Widmer, and Hartenstein 2001). The multipath location-aided routing (MLAR; Nanda and Gray 2004) is an example of such protocols. MLAR use 3-D positional information, particularly a hybrid extension to the well-known LAR and GRID that works in 3-D. MLAR is a hybrid algorithm that uses multipath routing (alternate path caching) in 3-D. Specifically, MLAR replaces LAR with multipath LAR in GRID. MLAR shows better efficiency and scalability than LAR, AODV, and AOMDV in both 2-D and 3-D.

Predictive mobility and location-aware routing protocol (PMLAR; Lu and Feng 2005) is another type of protocol that includes mobility behavior in the design of the protocol, as well as a prediction mechanism of the destination node. The region for packet forwarding is determined by predicting the future trajectory of the destination node. The routing performance can be effectively improved by adopting the prediction mechanism of the proposed PMLAR algorithm. The operation of PMLAR includes three phases: location service, route discovery, and route maintenance. When a source node S intends to transmit data packets to the destination node D , it needs to know the position of the destination node. Node S activates a location service to obtain the position information of D . Figure 4 demonstrates the location predication of PMLAR. As the figure shows, node S will initiate a flooding process to send out the request packet

to obtain D 's position information. Following rebroadcast by the intermediate node, the destination node D is informed that a position request has been initiated by S . Node D will start the prediction mechanism to compute the radius of a predicted zone. Then it sends back to node S the position, time stamp, and velocity of node D .

After it receives the position information of node D , source node S sends a route request (RREQ) message to initiate the route discovery process. The selection of a forwarding node, denoted by node N_i in the figure, is confined within the request zone, which is a rectangular region defined by the predicted zone as shown in Figure 4. Following receipt of the RREQ packet from S , N_i will verify whether it is located within the request zone. If the criterion is satisfied, N_i will record itself on the routing information within the RREQ packet header and rebroadcast the packet to the next node N_j . The process continues until node D is reached, upon which D will send out the route reply (RREP) packet to the source node S via the reverse route. Simulation results show that the PMLAR algorithm outperforms other routing protocols under different network topologies.

The adaptive cell relay (ACR) routing protocol is presented in Du and Wu (2006). ACR targets MANETs that have a varied density. It divides the routing area into square cells in which each cell contains one node. ACR combines three techniques to get a scalable, low-delay, and energy-aware routing protocol. These techniques are: cell relay (CR) routing for dense networks, large cell (LC) routing for sparse networks, and an adaptive scheme to detect network density changes to select the suitable routing technique. CR is an on-demand protocol based on source routing in which the source records all of the cells that lie on the direct line drawn between the source and the destination cells. Next, a route request packet from the source will be flooded to the recorded cells until

Figure 4: Location prediction in PMLAR

it reaches the destination. At that time, the destination will reply with a route reply packet so the source will know that a route exists. LC works in the same way as CR; the only exception is that the cell size is larger to reduce the probability of empty cells. To detect the density changes within the network, an adaptive head (AH) is selected. The AH stores the node count and the routing area boundary to calculate the density. The AH also receives a density change message from new nodes, nodes that have one of its neighbors die, or nodes that have moved outside of the network boundary. The AH adjusts the node count accordingly. ACR also features a technique that can detect when the network boundary shrinks. Based on the density changes, AH will flood a strategy change message to select the suitable routing technique.

Power-Aware Routing Protocols

Many power-aware routing protocols have been proposed from a variety of perspectives (Li, Cordes, and Zhang 2005). As stated earlier, although energy efficiency is important in MANETs, it is considered more important in WSNs. In general, power consumption depends on the position and the role of the node. For example, the cluster head in hierarchical protocols consumes more power than other nodes because they generate and route data continuously.

In Li, Cordes, and Zhang (2005), a survey of a number of energy-aware routing protocols in wireless ad hoc networks was performed. The routing protocols were broadly divided into five categories: active energy-saving protocols, passive energy-saving protocols, network lifetime maximizing protocols, topology control protocols, and energy-efficient multicasting and broadcasting protocols (see Figure 5). Li, Cordes, and Zhang provided a set of energy-aware protocols and comparisons between these protocols.

The multipath power-sensitive routing protocol (MPSR; Subramanian et al. 2004) is an example of power-aware routing protocols in which the objective is to improve the mean time to node failure and minimize the

energy variance between different nodes. In MPSR, the routing function constructs the routing tables depending on the remaining power of the nodes. A node will forward the packet to the path that will consume the minimum power. A maximum number of paths can be stored in the node; if no path is found, the node must initiate a route discovery process in which request messages are flooded in the network. Each node adds its remaining power and address to the route request message. When the message reaches the destination node, it calculates the average power and sends a reply message back to the source node including all nodes power and addresses that passed by it. Figure 6 shows the format of the message just described, in which node A is sending through a series of nodes (i.e., B, C, etc.) to the destination node. Simulation results show that MPSR works better than DSR in high-mobility circumstances with less packet loss rate.

In MPSR, every node in the network is treated equally, and the overall network is stable for a long time. Another interesting feature of MPSR is that the end-to-end packet delay does not increase significantly. Simulation results show that the performance of MPSR protocol outperforms traditional dynamic source routing.

Multicasting Protocols

The increase in the number of multicast applications in the wireless environment is considered the main motivation for developing the ad hoc multicast protocols. Multipath multicast routing algorithm (MRPM; Mao et al. 2003) is an example of such protocols in which the algorithm chooses the next hop based on cost factors. Another multicast protocol used in real-time applications and media streaming is the multipath real-time transport protocol (MRTP; Guven et al. 2005). This protocol is based on the real-time transport protocol (RTP) and the real-time transport control protocol (RTCP), which complete each other in end-to-end data streaming applications such as video and audio conferencing. The multiobjective multipath routing algorithm for multicast flows (MMRAM) is yet another multicast protocol. Multiple paths usually exist

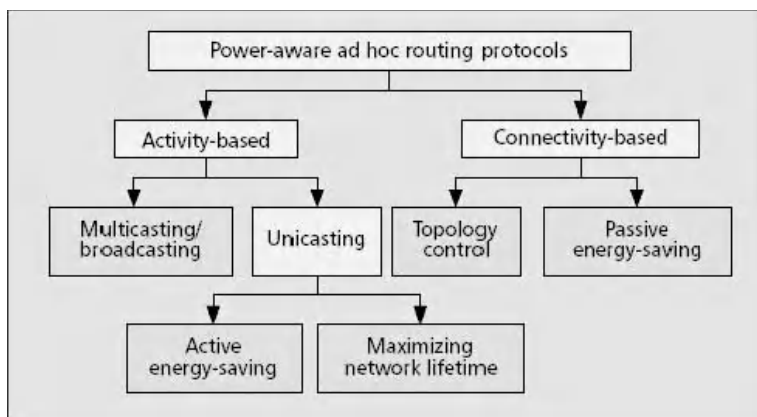

Figure 5: Categorization of power-aware ad hoc routing protocols

Addr A	P _A	Addr B	P _B	Addr C	P _C	Addr D	P _D
--------	----------------	--------	----------------	--------	----------------	--------	----------------	-------

Figure 6: Remaining power request/reply message

between any source and destination nodes. Such path diversity has been demonstrated to be effective in combating congestion and link failures for improved media quality. The multipath real-time transport protocol (MRTP) provides a convenient vehicle for real-time applications to partition and transmit data using multiple flows. It has been shown that, with one additional path, MRTP outperformed single-flow RTP by a significant margin. More simulation results were presented to demonstrate multicasting capabilities of MRTP.

Security Routing Protocols

The need for a secure end-to-end connection in wireless networks is of great interest; hence, many protocols were proposed to accomplish this task (Argyroudis and O'Mahony 2005; Yih-Chun and Perrig 2004). Multipath TCP security (MTS; Mao et al. 2003) is one such protocol in which the source node adaptively chooses the available route instead of testing the stored routes one by one. Therefore, the route of the TCP session is not fixed but changes continuously. The source uses route discovery to initiate multiple paths and the destination, and at the same time sends check packets to make sure that the route path is still alive. Hence, the source node has many route options from which to select the most secure path among them (Niculescu 2005).

The route discovery process described in earlier sections sends request messages to the network in which each message includes the packet type field, source address, destination address, broadcast ID, and hop count. The broadcast ID is incremented each time by one. When the message propagates, each node stores the message, increases the hop count, inserts its own address, and forwards it to the neighboring nodes. It is possible for the intermediate node to receive several copies of the same request, so the node stores the broadcast ID to eliminate duplicate copies. When the request reaches the destination node, it stores the messages and unicasts a reply message (that includes a reply ID instead of a broadcast ID) to the source node following the same path. Figure 7(a) shows the route request mechanism and Figure 7(b) shows the route reply.

This protocol was found to offer good performance and security. However, when the node movement speed

Figure 7: (a) Route request broadcast (b) Route reply unicast

increases, MTS delay increases significantly. Another method to secure the data is by dividing it into several chunks and then forwarding it to different paths. This method will secure confidentiality and reduce the chance of eavesdropping. At the same time, this will increase the collision among the paths and hence decrease the packet delivery ratio.

Many of the routing protocols for ad hoc networks were designed with no attention to security issues. Ad hoc networks are generally vulnerable to internal and external attacks. For example, the two well-known protocols DSR and AODV suffer from many security issues. In particular, redirection by modifying route sequence numbers or route direction is one such attack in AODV. Figure 8 presents an example in which an attacker is able to route data to himself from node B. Tunneling is another attack in which the attackers use a direct virtual channel among them as though they are adjacent to each other physically. The main idea of this attack is shown in Figure 9.

There are other attacks that generate false routing information to mislead the routing nodes. The *falsifying route errors attack* is an example in which some protocols, such as the DSR, depend heavily on the routing error messages to discover and maintain the paths between the source and destination. Table 1 summarizes the vulnerability of the DSR and AODV protocols to the previously mentioned attacks.

Solutions to the different previously mentioned attacks vary depending on the attack type and the network

Figure 8: General network topology

Figure 9: Tunneling attack

Table 1: Vulnerability of AODV and DSR

Type of Attack	AODV	DSR
Modify route sequence number	Yes	No
Modify hop count	Yes	No
Modify source route	No	Yes
Tunneling	Yes	Yes
Spoofing	Yes	Yes
Falsifying route errors	Yes	Yes
Broadcast falsified routes	No	Yes
Rushing attack	Yes	Yes

topology and metrics. Authentication during all routing phases is one of the proposed solutions. The trust-level metric is another proposed solution that mirrors the minimum trust value required by the sender. The trust level is embedded in the control messages, and nodes will not process the incoming packet unless it passes certain predefined trust levels. Security-aware routing (SAR), which is a modification of the AODV based on the security level described, is an example of such protocols. However, this approach better determines the trust level in hierarchal

topologies and requires more support (e.g., authentication) in other topologies.

Secure neighbor verification is one of the proposed solutions to checking the identity of neighboring nodes. It consists of a three-round message exchange between two nodes; they are considered neighbors if they exchange the messages successfully. If they do not, the two nodes are not physically neighbors because of the effect of one of the previously mentioned attacks. The main drawback of this approach is the increase in overhead when mobility increases.

Randomized message forwarding is used to minimize the effect of the rushing attack described previously. In this solution, the node selects one of the incoming RREQ packets randomly instead of forwarding the first received request immediately. With this approach, the probability of forwarding the vulnerable request decreases as the number of queued requests in each node increases. However, there is a trade-off between the number of queued nodes, increasing security, and increasing the overhead in the network. Table 2 summarizes the previously mentioned solutions.

A survey of secure ad hoc routing protocols for mobile wireless networks is presented in Patroklos, Argyroudis, and O'Mahony (2005). The surveyed protocols follow the table-driven and source-initiated on-demand approaches. The protocols were classified into five categories: solutions based on asymmetric cryptography; solutions based on symmetric cryptography; hybrid solutions; reputation-based

Table 2: Proposed Solutions Comparison

Proposed Solution	Prevented Attacks	Drawbacks
Authentication in all phases	<ul style="list-style-type: none"> - External and internal attacks - Spoofing - Redirection by modifying sequence number 	<ul style="list-style-type: none"> - Requires certificate authority or key sharing
Trust-level metric	<ul style="list-style-type: none"> - All attacks prevented by authentication - All attacks on higher trust levels nodes 	<ul style="list-style-type: none"> - Requires certificate authority or key sharing - Requires defining trust level

solutions; and a category of add-on mechanisms that satisfy specific security requirements.

Multi-Level Hierarchical Routing

To address the network scalability problem, hierarchical routing protocols are normally developed. In hierarchical routing protocols, the network is divided into a number of clusters of fixed or variable size. Inside each cluster, a node will act as a cluster head; all of the nodes in the cluster are within direct transmission range of the head. Sometimes, a node that lies in the transmission range of more than one cluster head is called a gateway and can be used by cluster heads to relay packets between clusters. Numerous hierarchical routing protocols have been proposed for MANETs and WSNs; a comprehensive review can be found in Perkins (2000). Here we briefly present several protocols that have been proposed recently. In hierarchical routing, the overhead and complexity are a result of the selection and maintenance of the cluster head. There are several algorithms to select a cluster head, including low-ID algorithm (Chiang et al. 1997), weighted algorithm (Basagni 1999), and highest-connectivity algorithm (Ye et al. 2001). When one cluster change causes additional leader changes in the network, this is called the *rippling effect*. The adaptive routing using clusters (ARC) protocol (Gerla and Tsai 1995) solves this problem by limiting the leadership changes so they only occur when one cluster becomes a subset of another cluster. When the number of mobile nodes increases further, multi-hierarchical routing protocols are developed to increase scalability. In a multi-hierarchical protocol, the heads of the clusters form a higher-level cluster, and a leader of this cluster will be selected, thereby forming a tree structure. The adaptive routing using cluster hierarchies (ARCH; Belding-Royer 2003) is a multilevel hierarchical clustering protocol that extends ARC. In ARCH, mobile nodes periodically exchange hello messages between neighboring nodes to build a cluster hierarchy. Safari is another hierarchical routing protocol, which claims to provide large-scale mobile wireless network connectivity and basic network services. It consists of three basic protocols: self-organization, scalable routing, and distributed address resolution.

The hierarchical LANMAR (H-LANMAR; Saha and Johnson 2004) is another multilevel hierarchical routing protocol. The key difference of H-LANMAR is that it assumes that there are some special nodes—called *backbone nodes* (BNs)—in the ad hoc network that are equipped with several powerful, long-range radios in addition to the general radios. The higher-level links can be established to connect the BNs to become a backbone network.

Multipath Routing Protocols

As a result of the dynamic characteristics of ad hoc networks, the wireless links tend to break. A new route has to be found before the source can continue sending packets, which will take time and increase delay. In multipath routing, multiple routes may be found between the source and the destination nodes. The advantages of multipath routing include load balancing, fault tolerance,

and higher aggregate bandwidth. In most MANETs, multipath protocols are needed to facilitate efficient connectivity between nodes that are not necessarily within each other's wireless range. Many routing protocols in MANETs preserve a caching mechanism by which multiple routing paths to the same destination are stored. Multipath routing is essential for load balancing and offering quality of service. Other benefits of multipath routing include: the reduction of computing time that routers' CPUs require, high resilience to path breaks, high call acceptance ratio (in voice applications), and better security. However, excessive power consumption and congestion can occur if the protocol is not designed carefully.

The disadvantages of multipath routing protocols, compared to unipath protocols, are their complexity and overhead (Mueller and Ghosal 2004). A new routing metric, the route outage probability (ROP), is proposed for channel fading environments with single and multipath routing (Park, Andrews, and Nettles 2003). ROP is defined as the probability of packet transmission failure in a route due to channel fading, and can be represented by the average received signal-to-noise ratio (SNR). In multipath routing, ROP is used with the multiroute path selection (MRPS; Souryal, Vojcic, and Pickholtz 2001) scheme to select a certain number of routes to the destination for the source and intermediate nodes. In Ye, Krishnamurthy, and Tripathi (2003), a multipath extension to AODV, called AODV-multipath (AODVM), was proposed. Multiple disjoint routes can be found using the AODVM route discovery process. A recent paper (Ganjali and Keshavarzian 2004) provides a contradictory conclusion to the widely accepted belief that multipath can significantly improve network balance by numerical analysis and simulations. When we choose the shortest path, the route is actually very close to the line that connects the source and destination in a dense ad hoc network, and the traffic in the center of the network is heavily loaded (Ganjali and Keshavarzian 2003). Unless a very large number of paths are used (e.g., 100), multipath has a similar effect on load balance as unipath.

Ducatelle, Di Caro, and Gambardella (2005) describe the hybrid algorithm AntHocNet, an ACO algorithm for routing in MANETs. The route setup of this scheme is performed by reactive algorithm; the route probing and exploration are performed by proactive scheme. The related simulation experiments show that AntHocNet can outperform AODV in terms of delivery ratio and average delay, especially in more mobile and larger networks. Scalability is also promising in this scheme. However, potential drawbacks include relatively large amounts of overhead and reduced adaptability to the network situation.

Hierarchical routing protocols tend to avoid excessive overhead by limiting the local traffic to the local management—only global movements are reported between zones and hierarchical layers. This, on the other hand, increases the complexity of the routing schemes. In Bohacek et al. (2005), a technique is proposed to reduce the computational complexity of max-flow routing, based on a hierarchical decomposition of the network (hierarchical max-flow routing, or HMFR). Max-flow routing forwards packets in such a way that the impact of failures is minimized. However, the computational

complexity of max-flow routing is quite high; therefore, it is not reasonable for moderate-size networks. Other hierarchical routing protocols—such as hierarchical state routing (HSR), zone-based hierarchical link-state routing protocol (ZHLS), and clusterhead gateway switch routing (CGSR)—fall under the same category. The multipath routing algorithms used in Li and Kwok (2005) do not rely on a centralized encryption facility (e.g., a public key infrastructure [PKI] server) or complicated distributed keying protocols. The algorithm, called multipath TCP security (MTS), enhances data security by having source nodes adaptively choose the available routes rather than exhaustively testing the stored routes one by one. Simulation results show that the algorithm provides a reasonably good level of security and performance.

Table 3, adapted from Adibi and Erfani (2006), provides examples from the protocols proposed for MANETs and compares them according to the classification map

shown in Figure 1. Note that this is not an exhaustive list of the protocols surveyed in this chapter.

ROUTING PROTOCOL IN WIRELESS SENSOR NETWORKS

The main task of sensor nodes in WSNs is to collect specific data from the surrounding environment and then route it to the base station (BS, also known as sink) node. Routing protocols in WSNs have tried to address many common design issues such as power conservation, data security, node positioning, and data collection and aggregation problems. Many routing and data dissemination protocols have been proposed for WSNs. In general, routing in WSNs can be broadly divided into flat-based routing, hierarchical-based routing, and adaptive-based routing depending on the network structure. Furthermore, these protocols can be classified into

multipath-based, query-based, negotiation-based, or location-based routing techniques depending on the protocol operation. Next, we provide a brief overview of the most relevant studies; a detailed survey on routing techniques in WSNs can be found in Al-Karaki and Kamal (2004) and Niculescu (2005).

One of the main aspects of sensor networks is that the solutions tend to be very application specific. Thus, three main paradigms for communication in ad hoc sensor networks have been investigated, namely, node centric, data centric, and position centric (Niculescu 2005). In the node-centric scheme, protocols perform routing among nodes based on names, and data can be routed independently from upper layers and can recover from node failures easily via route redirection.

Data-Centric Routing Protocols

In the data-centric approach, redundant data will be aggregated in order to save energy. Intanagonwiwat, Govindan, and Estrin (2000) proposed a popular data aggregation paradigm for WSNs called *directed diffusion*. Using this method, all data generated by sensor nodes are named by attribute-value pairs. The BS requests data by broadcasting interests. An interest, which describes a task required by the network, diffuses through the network hop by hop and draws gradients that satisfy the interest toward the BS. When interests fit gradients, paths of information flow are formed; some paths are reinforced to prevent further flooding according to a local rule. In order to reduce communication costs, data are aggregated on the way. The operation of directed diffusion is shown in Figure 10.

The minimum cost forwarding algorithm (MCFA; Ye et al. 2001) exploits the fact that the direction of routing is always known, that is, toward the fixed external base station. Hence, a sensor node needs only to maintain the lowest cost route estimate from itself to the BS. Heinzelman, Chandrakasan, and Balakrishnan (2000) introduced a hierarchical clustering algorithm for WSNs called the low-energy adaptive clustering hierarchy (LEACH). LEACH is a cluster-based protocol that includes a distributed cluster formation in which the sensors elect themselves cluster heads with some probability. Cluster head nodes compress data that arrive from nodes that

belong to the respective cluster and send an aggregated packet to the BS. Although data processing can take place anywhere in the network, LEACH achieves energy savings by processing data at its cluster head nodes. In Bandyopadhyay and Coyle (2003), results in stochastic geometry were used to derive solutions for the values of two parameters (the number of hops to reach a cluster head and the probability of becoming a cluster head) of a modified max-min d-clustering algorithm to minimize the total energy.

A cost-aware dynamic routing protocol, Tempere University of Technology WSN routing (TUTWSNR), is presented in Suhonen et al. (2006). TUTWSNR considers multiple cost metrics at the same time to find the optimal path. These metrics include delay, reliability, and energy. It uses the same technique that is used in directed diffusion to construct (sink-initiated) routes during the network initial setup; the only exception is that the sink does not need to refresh the interest periodically. Gradients are created from sources to destinations in which the node with the lowest cost will have a high gradient. To allow mobility, add flexibility, and recover from route failures, alternative node-initiated routes are created; this corresponds to the maintenance phase. The cost function is used to determine the next hop cost. It tends to maximize route reliability, minimize energy consumption, minimize delay, and balance node load.

Energy-balancing multipath routing (EBMR; Chen and Nasser 2006) extends the network lifetime using multipaths alternately; the BS is responsible for establishing, maintaining, and selecting the best route. The BS depends on the current energy level of the nodes that are constructing the route to select the route with the minimum energy cost. EBMR reduces the communication and routing overhead within the network. Sensor nodes need not maintain up-to-date routing information; they only need to know the current routes toward the BS. Wu and Havinga (2006) propose a reliable cost-based data-centric routing (RCDR) protocol. RCDR utilizes data aggregation and two types of gradients: local and global. Based on the local gradients, data from nodes around the event are routed toward the vent-originated node (local maxima). The local maxima node aggregates the data and sends the final report to the BS. The global gradient is used to establish routes between the local maxima and the BS. RCDR tolerates sink or BS movement without

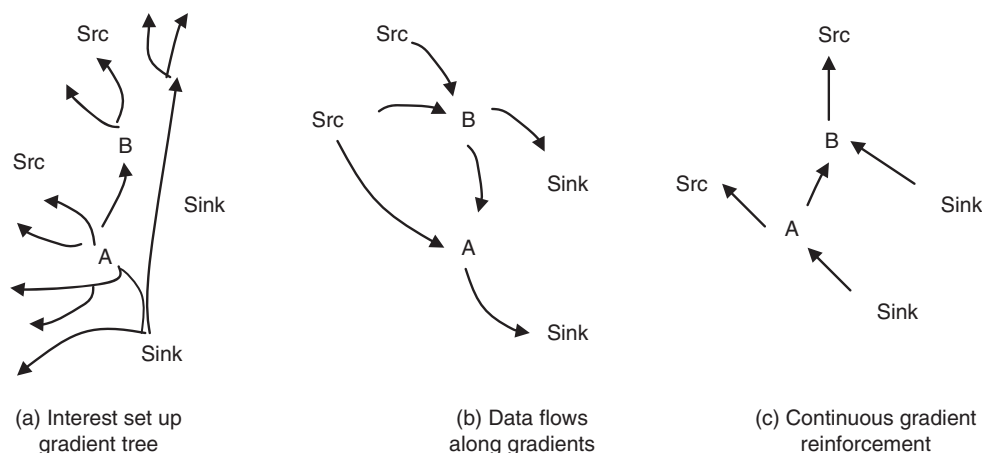

Figure 10: Directed diffusion routing approach (Intanagonwiwat, Govindan, and Estrin 2000)

the need to reset the network to restore gradients. This is done via negative gradients based on queries sent from the sink to its old local neighbors.

Position-Centric Routing Protocols

This approach uses nodes' positions to identify node and route data to the destination. This protocol introduces several problems, such as defining a positioning system and node positioning. Node positioning is related to the geography of the field and line-of-sight problems. Using a global positioning system is a power-aware challenge. Once the source knows the position of the destination node, it forwards the data to the nearest node to the destination. Routing tables are not needed in this approach, and it is also independent from mobility when the positions of intermediate nodes are known. However, the main disadvantage of position-centric routing protocols is that the source must know the position of the destination to forward the data. Position-centric protocols can combine other factors with regard to route construction in addition to the distance to the BS. For example, geographic and energy-aware routing (GEAR; Yu, Estrin, and Govindan 2001) depends on both the energy level of the next node and the distance to the BS to find the optimal route. A geographic routing algorithm (GERA) is presented in Santos et al. (2006). GERA begins its work by dividing the nodes into clusters. This is accomplished by sending hello messages that contain the node location and its power status. The cluster head is the first node that sends the hello message. Next, the source looks for the sink location and forwards the data to the closest reachable node to the BS. Table 4 summarizes the differences among different wireless sensor network paradigms.

It was concluded in Niculescu (2005) that the position-centric approach, although the oldest and best understood, is not the most appropriate for large-size, low-energy, application-specific sensor networks.

Node-Centric Routing Protocols

In node-centric routing, target nodes are explicitly addressed by source nodes. The target node can be a single

node, a group of nodes, or the set of all nodes in the network. In other words, we may have unicast with one destination, multicast with several destinations belonging to one group, or broadcast when sending to all nodes.

In this type of routing, nodes play a key role in the operation of the routing protocol. In particular, the probability of node failure and environmental effects on sensor nodes receives considerable attention in the literature. One of the most well-known solutions for this problem is path redundancy; modified flooding algorithms and gradient broadcast are two examples of these methods (Koubaa and Song 2004). In flooding-based protocols, each node sends a received packet to some of its neighbors. As a result, a packet will reach the destination via many paths, which will guarantee the correct delivery of the packet. This is one advantage of flooding. Other advantages of flooding include simplicity, reliability, scalability, and system robustness. However, flooding has very poor performance because a large number of copies of a packet is disseminated throughout the network. Modified flooding algorithms have been proposed to improve flooding performance. These protocols use geographical information and reduce the number of copies of a packet distributed in the network by reducing the number of unnecessary relay nodes and equivalent relay paths. In these modified algorithms, there is a trade-off between energy consumption and network robustness.

Gradient broadcast (Koubaa and Song 2004) is another routing protocol that addresses the problem of robust data forwarding using unreliable sensor nodes with error-prone wireless channels. In this algorithm, the sink builds and maintains a cost field. Each node keeps the cost for forwarding a packet from itself to the sink. Nodes closer to the sink have smaller costs. Because multiple paths exist between a source and the sink, a source assigns a credit to each report it sends out to control the degree of path redundancy. The credit is some extra budget that enables a packet to be forwarded over multiple paths, each of which has a cost no greater than the total budget of the credit plus the cost of the source. The amount of credit determines the width of the paths, thus the degree of robustness and overhead.

Table 4: Comparisons among Three Routing Approaches in WSNs

	Node Centric	Data Centric	Position Centric	Energy Centric
Compatibility	Yes	No	N/A	Yes
Layered	Yes	No	Yes	Yes
Additional Requirements	Yes	Yes	No	Yes
Routing:				Yes
-				Yes
Mobility				
-	No	No	Yes	
Scalability	No	Yes	Yes	
Discovery	No	Yes	(Some support)	(Some support)
Querying	No	Yes	No	No

Another protocol is the node-centric load-balancing algorithm for wireless sensor networks (Dai and Han 2006). The idea is that by spreading the workload across a sensor network, load balancing reduces hot spots and increases the energy lifetime of the sensor network. In Dai and Han (2006), a node-centric algorithm was proposed to construct a load-balanced tree among sensor networks of asymmetric architecture. The algorithm achieves routing trees that are more effectively balanced than routing based on breadth-first search (BFS) and shortest path obtained by Dijkstra's algorithm.

Energy-Centric Routing Protocols

As stated earlier, saving energy consumption is one of the main challenges in WSNs. A massive number of studies in the WSN research are concerned with saving energy in all protocol stacks designed for WSN. A number of these protocols appear in Al-Karaki and Kamal (2004). However, more recent studies that tackle the same issue have also been introduced. Among these protocols is the link quality estimation-based routing protocol (LQER) (Koubaa and Song 2004), in which the link quality is estimated with (m,k) -firm. The basic idea of link quality estimation based on (m,k) -firm is that at least m out of any k consecutive deadlines in task windows must be met by the task flow. Based on this idea, (m,k) -firm-based link quality estimation can be designed (i.e., if m out of k history packets are transmitted successfully, the link quality is qualified). In application, a suitable value of k will be determined in different environments. Through simulation, it can be found that when $k=9$, (m,k) -firm link quality can meet the requirements of minimum energy saving. LQER is designed based on a minimum hop field-based routing protocol that has an objective of high energy efficiency (Zhuchang and Yining 2004). The main idea of minimum hop field-based routing protocol (Tong and Culler 2003) is for each node to remember the node with minimum hop that is one hop smaller than itself in all one-hop-away neighboring nodes. When data are to be delivered, one node can be specified from the set of all eligible nodes to be a transmit node. As shown in Figure 11, assume that the minimum hop of node S is 7, and its transmission node set includes four nodes—D, C, E, and A—with a node hop of 6. In this way, it can be guaranteed that data are delivered through the shortest path without producing redundant information. When a node

Figure 11: An example of minimum hop field-based routing protocol

transmits data, all of its one-hop-away neighbors receive the packet, but only the node specified in the packet will actually transmit the packet. Packets are transmitted to the base station in this way via the shortest path.

A more recent study on energy-centric routing in WSNs appeared in Ye et al. (2005). The main idea is to build a tool, called an energy-centric scale (ECscale), which continuously monitors the status of energy resources following network deployment. The information on energy status can be used to early-notify both the sensors and deployers of resource depletion in some parts of the network. It can also be used to perform energy-efficient routing in WSNs. Optimal as well as approximate energy-centric routing in WSNs, with the objective of maximizing the network lifetime, was proposed. Simulation results show that this scheme is scalable and can provide many levels of energy savings when compared to conventional routing schemes.

CONCLUSION

This chapter surveyed a number of contemporary papers that explore routing protocols in wireless mobile ad hoc and sensor networks. The design of such protocols spans a wide array of parameters. This chapter tried to encapsulate the previous studies in this field and present a detailed categorization along several parameters such as underlying structure, path cardinality, and type of operation. Overall, the surveyed protocols can be divided into the following categories: proactive, reactive, position, energy, secure, flat, and hierarchical routing protocols. Designing a good energy-efficient routing protocol for ad hoc wireless networks is still a challenging task. Although extensive efforts have been exerted thus far on the routing problem, there are still some challenges facing effective solutions of the routing problem. First, there is a tight coupling to the physical world and embedded in unattended control systems. Second, sensors are characterized by a small footprint; as such, nodes present stringent energy constraints because they live with a small, finite energy source. This also differs from traditional fixed but reusable resources. Third, more work on the development of power-efficient multicasting or broadcasting protocols should be conducted, especially localized protocols. An interesting subarea is power-efficient geocasting, in which a packet is delivered to all nodes within a specific geographical region. Fourth, hierarchical routing is an old technique to enhance scalability and efficiency of the routing protocol. However, novel techniques of tiered architectures (a mix of form and energy factors) to network clustering for maximizing the network lifetime are a strong research area in WSNs. Fifth, time and location synchronization are needed, and energy-efficient techniques for associating time and spatial coordinates with data to support collaborative processing are also required. Finally, self-configuration and reconfiguration are essential to the lifetime of unattended systems in dynamic, constrained energy environments. This is important for keeping the network up and running. As nodes die and leave the network, update and reconfiguration mechanisms should take place. An important feature in every routing protocol is to adapt to topology changes very quickly and to maintain network functions.

ACKNOWLEDGMENT

The author would like to express his deep thanks and gratitude to Ashraf Ali, Fadi Shehab, and Ghada Al-Mashaqbeh for their help in preparing parts of this article. We also appreciate the feedback, comments, and advice by anonymous referees, which helped improve the article quality.

GLOSSARY

Data-Centric Routing: A routing approach in which data are collected based on specific attributes.

Energy-Centric Routing: A routing approach in which routing decisions are based on energy concentrations in network regions.

Flat Network: A network in which each node plays the same role.

Hierarchical Network: A network in which a set of nodes is selected to act as superior layer(s) and perform a set of specific functions.

Location-Based Routing: A routing protocol in which the positions of nodes are used in forwarding the packets toward the destination nodes.

Mobile Ad Hoc Networks: A collection of wireless mobile or static nodes that dynamically form a temporary network without the use of any existing network infrastructure or centralized control.

Negotiation-Based Routing: A routing approach in which nodes negotiate data attributed before data are really exchanged.

Proactive Routing: A routing protocol in which a set of routes are found and stored for current and future use.

Quality of Service: A set of primitives that govern the quality of the data exchanged between nodes (e.g., end-to-end delay).

Reactive Routing: A routing protocol in which routes are only found when needed and no state information is maintained.

Routing: Moving data between a pair or a group of nodes such that certain requirements are met.

Wireless Medium: The open air that is shared among wireless nodes; its characteristics can vary with time.

Wireless Sensor Networks: A collection of wireless sensor nodes that are deployed either randomly or in predetermined locations to sense, collect, process, and communicate raw data.

INTRODUCTION

We consider dynamic wireless networks in which each node has the same and fixed transmission range. Ad hoc wireless networks are considered in conference, rescue, and military scenarios, while small size battery powered sensor networks are envisioned for monitoring the environment, with individual sensors reporting observed events (movement, temperature, chemicals, etc.) to a base station. The physical layer is approximated by assuming that a message sent by one of nodes is received correctly by all neighbors located within the transmission range (*one-to-all* communication). Among the common problems found in ad hoc and sensor networks is *broadcasting*, where a message is to be sent from one node to all hosts of the network. Applications of this broadcasting communication include route discovery, information dissemination, and synchronization.

Because of limited range of radio waves, a host is normally unable to directly communicate with all the recipient nodes. To fulfill a broadcasting task, many hosts thus have to act as routers by relaying the message to their physical neighbors. The simplest procedure is to have each node relay the message (exactly once) to its neighbors. This straightforward solution is known as *blind flooding* and is part of the IETF standardized *dynamic source routing* (DSR) protocol, described by Johnson et al. 2004. However, in non-sparse networks, this solution generates a lot of redundancy and collisions that could possibly prevent the broadcasting from being correctly performed. This issue, studied by Ni et al. 1999, is known as the *broadcast storm problem*. Moreover, significant energy is consumed by the redundant messages, which is an important consideration in low power sensor nodes.

A number of other broadcast protocols, more energy-efficient, have been proposed to replace blind flooding. Some of them are *centralized*, where nodes need to know the global topology of the network. In ad hoc or sensor networks, this causes a huge and unacceptable overhead for information exchange. Moreover, this information generally has a low lifetime due to frequent topology modifications

which occur because of mobility and changes in activity status from active to sleeping and vice versa.

Ad hoc and sensor networks require protocols, called *localized*, that rely only on local information that can be easily and quickly acquired. Methods covered here require each node to know the position of all its neighbors (1-hop positional knowledge), or the list of all its direct neighbors and their neighbors (2-hop topological knowledge). These protocols also need to be *reliable*. The reliability of a broadcast protocol refers to its capability of reaching all nodes connected to the source, assuming an ideal MAC layer. A high or even perfect delivery ratio is required for most applications.

Localized broadcast protocols covered in this chapter provide reliable broadcasting. They can be divided into two categories:

- *Self-pruning* schemes: each node locally decides whether to forward the packet. We describe several existing definitions, including a general definition by Wu and Dai, 2003 for *k*-hop neighborhood information, and *L*-hop forwarding history.
- *Neighbor-designating* schemes: each node is told by the upstream sender whether it needs to forward the packet. This can be done either via the data packet or via a previously sent control packet.

Williams and Camp (2002), comprehensively compared existing broadcast methods. Neighbor knowledge algorithms were claimed to be better suited to ad hoc networks than other approaches. Their comparison, however, did not include dominating set-based broadcast protocols, and did not consider any neighbor elimination scheme. Therefore, we believe that the best existing methods were overlooked in that paper, which motivated us to perform the comparison in this chapter.

We simulated the best existing localized schemes, and present here major comparative data. Among all the examined schemes, an enhanced definition for computing connected dominating sets seems to give the overall best results.

PRELIMINARIES

It is assumed that nodes all have the same transmission radius R . Two nodes are neighbors, and can communicate, if the distance between them is no more than R . This assumption is referred to as the *unit disk graph* model. The set of nodes is noted as V and the set of neighbors of a node u is noted as $N(u)$. The set of k -hop neighbors of node u , including u itself, is noted as $N^k(u)$. The degree of u is its number of neighbors and the density of the network is the average degree of nodes. Each node u is assigned a unique identifier $id(u)$, which may be an IP or a MAC address. Finally, the distance between two nodes u and v is measured in number of hops, which is equal to the minimum number of edges to cross from u to v . In Figure 1, the distance between nodes a and h is 3 hops. The degree of node a is 3. The set of 1-hop neighbors of a is $\{b, c, e\}$, and the set of its 2-hop neighbors is $\{d, f, g\}$.

Nodes have a k -hop knowledge if they know each neighboring node within a distance of k hops. This knowledge is acquired using regular HELLO messages. The two selected protocols use either $k = 1$ or $k = 2$, mainly depending on whether or not positional (geographic) information is available. Geographic position and distances between neighbors may be obtained by using a location system such as the *global positioning system* (GPS) and by including locations in HELLO messages.

In the graph representing the 2-hop knowledge at each node, there is a difference between topological and positional information that may be used. If position information is available, each node may conclude, based

Figure 1: A sample network

Figure 2: Topological information vs. positional information

on their locations, whether two of its 2-hop neighbors are neighbors themselves. Such a conclusion cannot be made without position information (that is, based solely on topological information), and therefore, no edge between such neighbors is assumed. Figure 2 illustrates the difference between these two assumptions, considering node a . With topological information, in Figure 2(a), the 2-hop neighbors $\{c, e, f, g\}$ are assumed to not be directly connected. This is not the case with positional information in Figure 2(b). Note that node c is always known to be a common neighbor of nodes b and d because it appears in both neighborhood lists.

BROADCASTING PROTOCOLS

Multipoint Relay Protocol

The *multipoint relay* (MPR) protocol was proposed by Qayyum et al. (2002) and belongs to the family of neighbor-designating methods. In this algorithm, it is assumed that nodes have a 2-hop topological knowledge. Each node u that has to forward the message first selects a subset of relays among its 1-hop neighbors that covers the same 2-hop nodes as the complete set of 1-hop neighbors does. Such a set is called a multipoint relay set. Here, node a covers node b if a and b are 1-hop (direct) neighbors. For example, nodes c and e (1-hop neighbors of a) in Figure 1 cover nodes d, f, g (2-hop neighbors of a). The selection is then forwarded within the packet so that receivers can determine whether they have been selected. Each node that receives the message for the first time checks if it is designated as a relay node by the sender. In this case, the message is forwarded after the selection of a new relaying set of neighbors. A variant exists in which nodes select their relays before having to broadcast a packet, in a *proactive* manner, and selection is sent within HELLO messages.

Obviously, it is important to select small sets of relays. Finding such a set of minimal size is known as the *minimum set cover* problem and is described by Garey and Johns (1979) as a NP-complete problem. A greedy heuristic was proposed by Quayyum et al. (2002) and was first described by Lovasz (1975). Considering a node u , it can be described as follows:

1. Place all 2-hop neighbors of u in a set $MPR'(u)$ of uncovered 2-hop neighbors.

2. First select all 1-hop neighbors of u that are the only possible relays for some 2-hop neighbors. Relays are placed in $\text{MPR}(u)$, and covered 2-hop neighbors are removed from $\text{MPR}'(u)$.
3. While the set $\text{MPR}'(u)$ is not empty, repeatedly select the 1-hop neighbor not already selected that covers the greatest number of nodes in $\text{MPR}'(u)$. Each time a new node is added to $\text{MPR}(u)$, remove its neighbors from $\text{MPR}'(u)$. In case of a tie, choose the node with the highest degree.

An example of this heuristics is given in Figure 3, where f is the source node. The algorithm starts with $\text{MPR}(f) = \phi$ and $\text{MPR}'(f) = \{a, b, e, i\}$. The node c is the only one able to reach a , so it is added to $\text{MPR}(f)$, and nodes a and b are removed from $\text{MPR}'(f)$. No other mandatory 1-hop neighbor of f exists, so other relays are selected according to the number of nodes in $\text{MPR}'(f)$ that they cover. Nodes d and h each cover only one node in $\text{MPR}'(f)$, while node g covers both e and i at the same time. Therefore, g is chosen and added to $\text{MPR}(f)$. The set $\text{MPR}'(f)$ being empty, no other nodes are selected.

Connected Dominating Sets

In Figure 4(a), a sample network is given in which each white node has a black neighbor in its 1-hop neighborhood. The set of these black nodes $\{c, g\}$ is called a *dominating set*, and these nodes are said to be *dominant*. More formally, a subset $V_D \subseteq V$ is said to be dominating if each node either belongs to V_D , or has at least one neighboring

Figure 3: Applying MPR at node f : $\text{MPR}(f) = \{c, g\}$

(a) A dominating set $\{c, g\}$

(b) A connected dominating set $\{c, g, h\}$

Figure 4: Two dominating sets

node that belongs to V_D . A *connected dominating set* (CDS), illustrated in Figure 4(b), may be used for broadcasting. In CDS based broadcasting, each node, receiving the packet, will retransmit it if and only if it belongs to selected CDS. Let us suppose that node e wants to broadcast a message. It sends the message to nodes a and g . Node g is dominant and therefore forwards the message to nodes f, h , and i . Node h forwards the message to c and d , and node c forwards it to node b .

A centralized heuristics by Guha and Khuller (1998), can be described as follows. Each node is initially colored white. The densest node in the graph is then colored black, and all its neighbors grey. Then, while there are some white nodes, the grey node with the largest number of white neighbors is selected, colored as black node, and all its white neighbors as grey nodes. Ties can be resolved by using some keys (identifiers). At the end, the set of black nodes is a CDS. This algorithm provides low numbers of nodes in CDS but it cannot be efficiently applied in a decentralized network. However, the size of the resulting set provides a good estimate of the limits one can reach with localized heuristics.

Coverage by 1-Hop Neighbors

Wu and Li (1999) proposed an algorithm that has been later improved in terms of message overhead by Stojmenović et al. (2001) and Stojmenović (2004). A node is referred to as *intermediate* if it has at least two 1-hop neighbors not directly connected. A node u is covered by a neighbor v if any other neighbor of u is a neighbor of v , and if v has a higher key than u . Nodes that are not covered by any neighbor are called *inter-gateway* nodes. A node u is covered by two directly connected neighbors v and w if any other neighbor of u is a neighbor of either v or w , and if v and w have higher keys than u . Inter-gateway nodes that are not covered by any pair of connected 1-hop neighbors become *gateway* nodes. As proven in Stojmenović et al. (2001) and Stojmenović (2004) each node can decide whether or not it is an inter-gateway or a gateway node without exchanging any message with its neighbor (assuming 1-hop positional or 2-hop topological information is available via HELLO messages), and the obtained set is indeed a CDS.

This rule has been further improved in terms of number of dominating nodes by Dai and Wu (2003). They proposed

a more general rule where by coverage may be provided by an arbitrary number of connected 1-hop neighbors. A modification of this *generalized self-pruning rule* has been proposed by Stojmenović and Wu (2004) in order to avoid similar message exchanges between neighbors.

Generalized Self-Pruning Rule. A node u is covered by a set of 1-hop neighbors A_u if A_u is connected, any other neighbor of u is also a neighbor of a node in A_u and any node in A_u has a higher key than u .

A simple algorithm for verifying this condition is proposed in Carle and Simplot-Ryl (2004), as follows. First, each node checks if it is intermediate. Then each intermediate node u constructs a subgraph G_h of its 1-hop neighbors with higher keys. In the graph composed of $N(u)$, each node which has a lower key than u is removed, as well as the corresponding edges. The resulting subgraph is denoted by G_h . If the latter is empty or disconnected, then u is in the dominating set. If G_h is connected but there is a neighbor of u which is not a neighbor of any node from G_h , then u is in the dominating set. Otherwise u is covered and is not in the dominating set. Dijkstra's shortest path algorithm may be used to test the connectivity. (It is performed locally at each node). Non-intermediate nodes are never dominant. This rule is illustrated in Figure 5, where identifiers of nodes are used as keys using lexicographical order for comparisons. Nodes $\{d, e\}$ are not intermediate because they do not have unconnected neighbors. The graphs G_h for nodes a ($\{e, g, h\}$), b ($\{c, f, i\}$), c ($\{d, f, h\}$), and f ($\{g, h, i\}$) are all connected, and cover neighbors with

Figure 5: Applying Dai and Wu's algorithm

Figure 6: Applying Dai and Wu's algorithm with different keys

lower keys. (Graphs G_h are indicated by their vertices only, respectively.) Thus, nodes a, b, c and f are not dominant. Only nodes g, h , and i decide to mark themselves as dominant. For instance, graph G_h for node g has vertices $\{i, h\}$ which are not connected, while this graph for nodes i and h is empty.

The key of a node may simply be its identifier, as used by Wu and Li (1999), or a pair (degree, id), as proposed in Stojmenović et al. (2001). For example, Wu et al. (2003) proposed this key for a node u :

$$\text{key}(u) = \{\text{energy}(u), \text{degree}(u), \text{id}(u)\}.$$

This means that nodes with higher energy levels have a higher probability of being elected as dominant. If the energy levels for two nodes are equal, then the second key, degree, is used for comparison. Finally, if there is a tie with the degree as well, the identifier is used. Figure 6 illustrates different sort of keys. In Figure 6(a), the key of a node is its identifier. In Figure 6(b) the degree is used as the primary key and the identifier as the secondary one. Some other keys were later proposed and studied by Shaikh et al. (2003).

Coverage by 2-Hop Neighbors

If positional information is not available, the described methods for covering neighbors by 1-hop neighbors all require 2-hop topological knowledge, because nodes need to know their neighbors and the neighbors of their neighbors. This knowledge, once available, could be better used by applying some enhanced concepts. To illustrate this, let us consider Figure 7(a) where the generalized self-pruning rule has been applied with identifiers as keys. The node a has been marked as dominant because it has two neighbors $\{b, f\}$, not directly connected, which are not covered by any set of neighbors with higher priority. In fact, a is itself covered by $\{b, e, f\}$ although e is not a 1-hop neighbor; and a could be marked as passive. While e is not a direct neighbor of a , this does not prevent the latter from verifying whether any of its neighbors are neighbors of e , or whether $\{b, e, f\}$ are connected, because e appears in the list of neighbors sent to a by its 1-hop neighbors, and therefore such a conclusion can be made. Similarly in 7(b), node b concludes that it is not dominant because

Figure 7: The enhanced definition of Dai and Wu's algorithm

all its neighbors $\{a, c, e\}$ as well as itself are covered by its connected higher key 2-hop neighbors $\{e, f\}$.

Therefore, we give an enhanced definition for computing a dominating set V_D , in general form (Wu and Dai 2003). We will later only discuss and implement the case $k = 2$, believing that the control overhead for $k > 2$ is prohibitive for use in practice.

Enhanced Dominating Sets. An intermediate node u is not dominant if there exists in its k -hop neighborhood a connected set A_u of nodes with either higher priorities or visited status, such that each neighbor of u either belongs to A_u or is a neighbor of a node in A_u .

Visited node status will be discussed in the next section, and, for now (in all definitions in this sub-section), we assume that u is not aware of any visited node.

Node u , if not dominant, must itself also be a neighbor of a node in A_u . To show that, assume that u has no neighbor in A_u , and consider its neighbor w with the highest key. Node w must be in the dominating set, because there does not exist another neighbor of u with higher key than the key of w , to cover u , which is a contradiction.

Note that when topological information is used, u is not aware of possible links between its 2-hop neighbors. It may therefore declare the set disconnected, although in reality it may not be (refer to Figure 2). This can be avoided by using positional information.

We now prove that this enhanced definition produces subset of nodes with respect to previous definition, and that it indeed produces a CDS.

Theorem 1. *The dominating set V_D obtained with the enhanced definition is a subset of the one obtained with the generalized self-pruning rule.*

Proof. In the generalized self-pruning rule, a node u is marked as not dominant if the subset of higher priority neighbors is connected and covers the neighborhood of u . As $N(u) \subseteq \hat{N}^2(u) \setminus \{u\}$, if there exists such a set in $N(u)$, then it also exists in $\hat{N}^2(u) \setminus \{u\}$. It can be derived that nodes marked as not dominant by the generalized self-pruning rule are also marked as not dominant by the enhanced definition. Only dominant nodes may be unmarked by the new definition.

Theorem 2. *For any given graph on which the enhanced definition is applied, each node u either belongs to V_D or is a neighbor of a node in V_D .*

Proof. Assume that the set V_D is not dominating. Let u be a non-dominant node with no dominant neighbor. Node u is covered by A_u , the set of 2-hop neighbors with higher key values than u . Let v be the node with the highest key value in $N(u)$. Node v has higher priority than u because of the existence of A_u and the need for at least one node from A_u to be 1-hop neighbor of u . Node v is not dominant because u is not covered by V_D . It is thus covered by a set A_v . Therefore, u is neighbor of a node w from A_v . Node w is therefore neighbor of u and has higher key value than v , which is a contradiction with respect to the choice of v .

Theorem 3. *For any given connected graph, there exists a path between any two nodes in the dominating set produced by the enhanced definition.*

Proof. We may assume that nodes are removed one by one in ascending order of priority instead of being removed simultaneously and will show that the removal of any node u preserves the connectivity. Let vuw be a path via node u . Node u is removed because of the set A_u , which is connected and covers its neighbors. Moreover, no nodes of A_u have already been removed since A_u contains nodes with higher priority than u . This means that there are two nodes v' and w' from A_u so that v is neighbor of v' , w is neighbor of w' , and v' and w' are connected in A_u . This means that nodes v and w remain connected after removal of node u . We can thus deduce that a node u will never remove itself from the dominating graph if there does not exist another path between any two components that are 'glued' together thanks to u .

These proofs are similar to the general proofs given by Wu and Dai (2003). All three proofs do not depend on the possible links between 2-hop neighbors. They are therefore valid for both topological and positional information. This does not mean that they will result in the same CDS. On the contrary, they can differ, because these additional links may be used to make connected a set of neighbors with higher priorities.

Figure 8: A new algorithm must be used for the enhanced definition

The algorithm described earlier for the general coverage by 1-hop neighbors is not applicable for this enhanced definition. Indeed, computing the graph G_h of neighbors with higher priority within the 2-hop neighborhood leads to nodes falsely marked as dominant, as illustrated by Figure 8. Node u is not dominant because there exists a connected set $\{v, w\}$ which covers $\{a, u\}$. However, the set G_h within the 2-hop neighborhood, $\{v, w, x\}$, is not connected. Using the original algorithm, u would have been marked as dominant. We therefore describe here a different algorithm from that presented in Wu and Dai (2003) for testing whether a node u will declare itself dominant, as follows. The algorithm takes $O(k^2d^2)$ time, where d is the average density.

1. Create a graph G_h composed from the nodes of higher priority than u (possibly including visited nodes) within the k -hop neighborhood of u .
2. Find the connected components in G_h ; this can be done by repeated application of Dijkstra's shortest path algorithm, starting each time from an unseen node. Alternately, depth first search or breath first search protocols may be repeatedly applied to find all components.
3. If there is a connected component which covers all 1-hop neighbors of u , then mark u as not dominant.

Other approaches exist for computing CDS. Wan et al. (2004) thus compute a very small (non-connected) dominating set and then compute a spanning tree to connect it. Because such methods have huge time and communication costs, we did not consider them in our evaluation. An extensive performance comparison of CDS construction algorithms, including such methods, has been done by Basagni et al. (2006). They focused on pure CDS algorithms, and did not consider additional mechanisms like the NES.

Neighbor Elimination Scheme

The *neighbor elimination scheme* (NES, or *wait and see*) described by Stojmenović and Seddigh (2000) and by Peng and Lu (2000) provides a simple way to eliminate redundant messages. In this method, when a node receives a message to broadcast, it sets a *timeout* period before transmitting. That is, nodes do not retransmit immediately, but wait for *timeout* duration while monitoring their

neighborhood. If all neighbors become covered during the monitoring time, then the node does not transmit. Otherwise, if the node's timeout expires and there are still uncovered neighbors, the node transmits. The timeout may be randomly chosen, or it may be computed based on several parameters. One solution is to let nodes with more neighbors rebroadcast earlier, so that more nodes can be covered by one transmission. We thus may define the timeout as $timeout = C \cdot numberUncovered$, where C is a constant and $numberUncovered$ is the number of neighbors that have not received the packet, based on node's knowledge. (Some neighbors could have received the packet from 2-hop neighbors that are not 1-hop neighbors; thus the node may not be aware of these transmissions). Ties can be resolved by using identifiers of nodes.

Figure 9(a) illustrates this scheme: node s sends a broadcast message to its neighbors b, d , and g . Each of these three nodes chooses a *timeout* duration inversely proportional to the number of its uncovered neighbors. For the sake of simplicity, let $C = 1$. Node b thus chooses to wait $1/2$ time units (TU), d chooses $1/3$ TU, and g chooses $1/2$ TU. At step 2 in Figure 9(b), node d transmits next and forwards the message to its neighbors a, b, c, h , and s . Node c sets up a timeout of $1/2$ TU and node a a timeout of 1 TU (because of g). Node h has no uncovered neighbors, so it does nothing. Note that a could also cancel the retransmission, but it is not aware that g already got the message from s . Node g now only has to wait $1/6$ TU, because $1/3$ time units have elapsed since it chose a timeout of $1/2$ TU. Node b now has only one uncovered neighbor, so it changes its original timeout to 1 TU, reduced by already elapsed time $1/3$, so its waiting time is $2/3$. At step 3 in Figure 9(c), node g forwards the message to a, f , and s , allowing a to cancel its retransmission. The remaining timeouts are $1/2$ for b and $1/3$ for c . Finally at step 4 in Figure 9(d), c forwards the message to b, d, e , and i . Node b thus cancels its retransmission.

We call a *relay candidate* a node which is in a multipoint relay set or in a connected dominating set. This scheme may be used as an added feature to improve the performance of existing broadcasting protocols. Regardless of the underlying algorithm, the NES can indeed be added to decrease the number of transmissions while still preserving the reliability, as follows. When a node receives the broadcasting message for the first time, two cases are possible. Either the node is not a relay candidate, in which case the packet is simply dropped, or it is a relay candidate, and then an NES is started, as described. During the NES, each 1-hop neighbor covered by other transmissions of the broadcast packet is removed from an internal list, which at first contains all the 1-hop neighbors, and timeout is adjusted. When the timeout expires, the forwarding is done only if the node still has uncovered 1-hop neighbors. Obviously, if all neighbors are covered by very first received message, the retransmission is canceled immediately without invoking NES.

We will now revisit the general definition of enhanced dominating sets, completing the notion of *visited nodes* already mentioned there. The case when NES is not applied will be referred to as the case of empty set of visited nodes, or the case with 0-hop forwarding history, according to the definition used in Wu and Dai (2003).

Figure 9: NES example

The application of NES to any of the methods will be referred to as the case of broadcasting with 1-hop forwarding history. In this case, the set of visited nodes is equal to the set of neighbors from which the message has been received. That is, visited nodes are exactly the nodes that have already retransmitted the packet. All neighbors of visited nodes are then eliminated by NES strategy. The node then applies coverage criterion to determine whether or not to retransmit. This means that the node waits for more information that would allow for a potential cancellation. If at the end of the timeout, there is still not enough information to allow the cancellation, then the transmission is performed. If the decision is to retransmit, then the node applies an additional *timeout* waiting period for possible enlargement of the set of visited nodes and hoping for subsequent cancellation of retransmission. Note that Wu and Dai (2003) did not discuss any analogous *wait and see* strategy.

The general case of L -hop forwarding history is also discussed and experimented with by Wu and Dai (2003). The case $L = 2$ corresponds to including, in the retransmitted packet, the identifiers of all neighbors from which this packet has been already received. The receiving node will then learn about all 2-hop neighbors which have so far retransmitted the message, and consider them as *visited* nodes in the general definition. While this method reduces the number of retransmissions, it also increases message length, adding to energy and bandwidth consumption. We therefore did not consider the case $L > 1$ in our experiments.

Connected Dominating Sets Based on MPR

Adjih et al. (2005) proposed a CDS election scheme based on MPR, later improved by Wu (2003). In this algorithm,

each node computes its multipoint relays and transmits the forward list to its neighbors. To do this, it requires a third round of HELLO messages after 2-hop neighborhood topology is gained. Each intermediate node decides to belong to CDS if it has either the smallest id in its neighborhood, or it is the multipoint relay of the neighbor with the smallest id. When MPR's are being selected, free neighbors are added first to the set of relays. A node u is a free neighbor of v if v is not the smallest id neighbor of u .

Figure 10 illustrates this algorithm. Nodes d and e are not intermediate, and thus are not dominant. Nodes a and b are intermediate and have the smallest id in their neighborhood; thus, they are dominant. Using the greedy heuristics by Qayyum et al. (2002) nodes g and h are the multipoint relays of a , and nodes c and f are the multipoint relays of b . Because they are MPR's of their neighbor with smallest id, they are thus dominant. The particular example given here does not reflect the real performance of the algorithm in most cases.

Figure 10: CDS obtained using the MPR-based definition

Broadcasting for Mobile Ad Hoc Networks

The techniques described so far assumed that the topology did not change since the last round of HELLO messages, and that topology does not change while broadcasting is in progress. To address moderate and high mobility scenarios that could violate this assumption, Stojmenović (2006) described the following broadcasting protocol. It adapts itself to all mobility scenarios, without tuning any parameter to change between static, moderate, and high mobility modes. This is important because other existing threshold-based approaches, switching between different protocols, may result in different protocols running at different nodes simultaneously, in addition to the incurred cost for gathering possibly suboptimal thresholds.

Nodes periodically exchange HELLO messages to update local knowledge up to two hops. The source node transmits the message. Upon receiving the message for the first time, each node initializes two lists: the receiver list (RL) of all nodes (up to a 2-hop distance) believed to have received the packet, and a list of neighbors in need of message (NN). The retransmission is cancelled if it is not in a selected connected dominating set. Otherwise a timeout waiting period is set. For each further message received, and its own message sent, every node updates RL, NN, and timeout. At the end of timeout, the node transmits if NN is non-empty. The message is memorized until T HELLO messages are received. The nodes add one bit to their HELLO message, indicating whether or not their list NN is empty, which is used in dominating set decisions. For each HELLO message received, NN is updated. Nodes that are no longer 1-hop neighbors are eliminated from the list, while new neighbors, not present in RL, are added. Regardless of previous decisions, all nodes that so far received the broadcast packet check whether new NN is non-empty. If so, they start fresh timeout.

EVALUATION OF PERFORMANCES

In this section, we provide experimental results about the performances of the selected protocols. The experiments were carried out in two phases. In the first phase, the performance of the basic schemes was evaluated. In the second phase, we added a neighbor elimination scheme to these algorithms and evaluated the performance of the resulting methods.

We use the commonly adopted random unit disk graphs, described earlier in this chapter, to model ad hoc networks. They are generated as follows: the network is always composed of 600 nodes randomly (and uniformly) placed in a square area which is scaled to obtain a given average degree. The radius R is set to be equal to 200 meters. For each measure, 500 broadcasts are launched and for each broadcast, a new *connected* network is generated. In connected graphs, the broadcast packet always reaches all hosts of the network because the broadcasting protocols are reliable.

We adopt certain assumptions to appropriately define the scope of our study. An ideal MAC layer is used, which provides for collision-free broadcasting. The hosts are static while broadcasting is in progress. Thus, any effect that mobility may have on the protocols is avoided. Because

of localized algorithms being applied, it is assumed that relative positions of nodes do not change sufficiently to impact the performance while broadcasting is in progress. Only one broadcasting task at a time is in the network and there is no other message traffic while broadcasting is in progress: thus, we avoid the impact of collisions in our experimental data. A protocol with a lower overhead on one broadcasting task is expected to maintain better performance relative to other protocols when collisions are considered. Each node retransmits packets (if it has to retransmit according to the protocol) only once. All its 1-hop neighbors receive this packet correctly. While a node transmits, none of its neighbors up to 2 hops are transmitting. This assumption was used to eliminate the problem of interference when a node receives two radio transmissions at the same time from two of its neighbors, which are not neighbors themselves.

The acronyms used are as follows:

- MPR: The multipoint relays protocol. The heuristics used is the original one proposed by Qayyum et al. (2002) and 2-hop neighbors already covered (and known as covered by the node) are not considered when computing multipoint relays for a given node.
- CH: Connected dominating sets using the centralized heuristics by Guha and Khuller (1998). This one thus has *global* information on the network.
- DW: Connected dominating sets using the definition by Dai and Wu (2003). The key of a node is equal to the record [degree, id].
- EDW: Connected dominating sets using the enhanced definition of DW, with topological information.
- EDWPOS: EDW with positional information.
- MPR-DS: Connected dominating sets based on MPR.

We first give the percentage of retransmitting nodes (noted PRN) in Figure 11. Figure 11(a) indicates that the MPR has a higher ratio compared to the other localized schemes. Moreover, each message in the MPR is longer. DW and MPR-DS behave equally well, this observation being consistent with results by Adjih et al. (2005). The enhanced definition EDW of DW gives better results than the latter as expected, and even better with positional information.

In Figure 11(b) we observe that the neighbor elimination scheme has significantly improved all localized schemes. It is interesting to note that all localized schemes obtain approximately same results after the addition of an NES. Not surprisingly, CH, as a centralized heuristics, always obtains very good results, and applying NES on top of it does not bring improvements. This is explained by the very low number of retransmitting nodes, and by the high distance between them, as will be shown later on. However, other schemes, while being localized, obtain close performance. When NES is applied, the number of relays in localized schemes is less than 1.5 times the one in CH. For the density of 30, the PRN of CH is equal to 7.8%, while the PRN of EDW is equal to 11.5%. This proves that localized schemes can be as good as centralized ones.

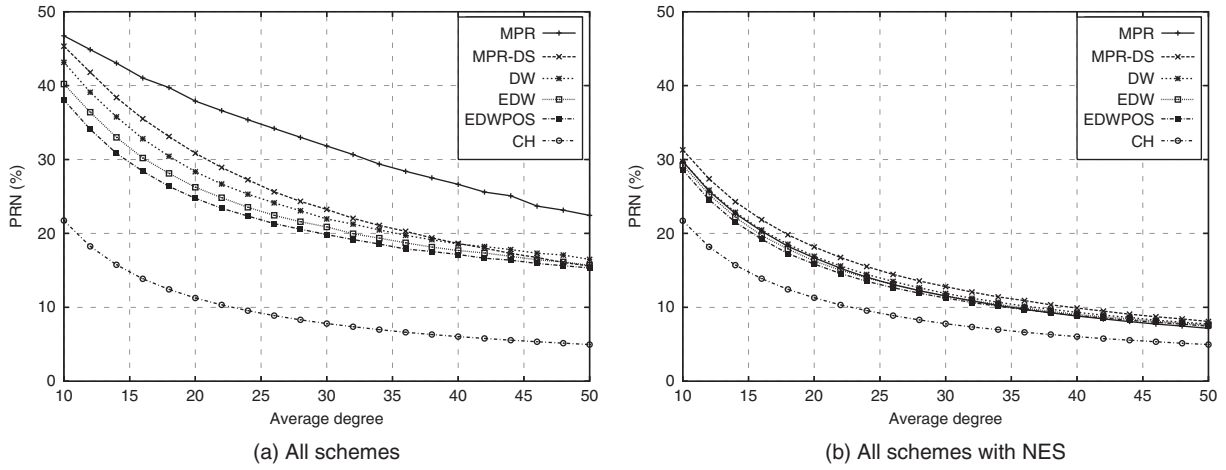

Figure 11: PRN versus average degree

We now give results about the number of times each non-transmitting node receives the message (NTN). CH has the best performance and the NTN values are relatively stable for all d values, while NES does not have a significant impact on it. In Figure 12, it is shown that MPR has the worst performance on this metric because as it seems to generate more redundancy, while other localized schemes obtain very similar results. We also observe that the number of received copies increases with the degree d , and that the neighbor elimination scheme is able to effectively reduce this redundancy. Indeed, as illustrated by Figure 12(b), nodes receive fewer copies of the same message, and traffic in the network is thus also greatly reduced. This improvement is obvious for all the localized schemes.

As with NTN, we measure the number of times each transmitting node receives the message (NTT). An observation similar to NTN can be obtained for NTT from Figure 13. That is, there is less redundancy in sparse networks than in dense ones. Recall that when the average degree d increases, fewer nodes retransmit the message. However, the number of times each node, transmitting or not, receives the same message increases. This can be

explained by the increased coverage of each transmission. According to our observations, it appears that the transmitting nodes receive more copies of the same message than non-transmitting nodes. Once again, we notice that the neighbor elimination scheme greatly improves the localized schemes, while CH does not benefit from it. It is interesting to note that, in the latter, each node receives approximately the same number of copies of the message, whether or not it is a transmitting node.

Finally, in Figure 14, we give a comparison of the CDS schemes in terms of the dominant graphs they produce. Figure 14(a) gives the average degree of the CDS; this is the average number of dominant neighbors per dominant node. Not surprisingly, this value is dependent on the average size of the CDSs: the smallest is the set, and the smallest is the average degree, so CH obtains the best results while other algorithms are somewhat equivalent, with a smaller degree for MPR-DS. An interesting remark is that the degree of the CDSs produced by the centralized heuristics is constant for every density and is always around the value of 2. We also consider in Figure 14(b) the average length of the edges between two dominant neighbors divided by R . This value seems relatively

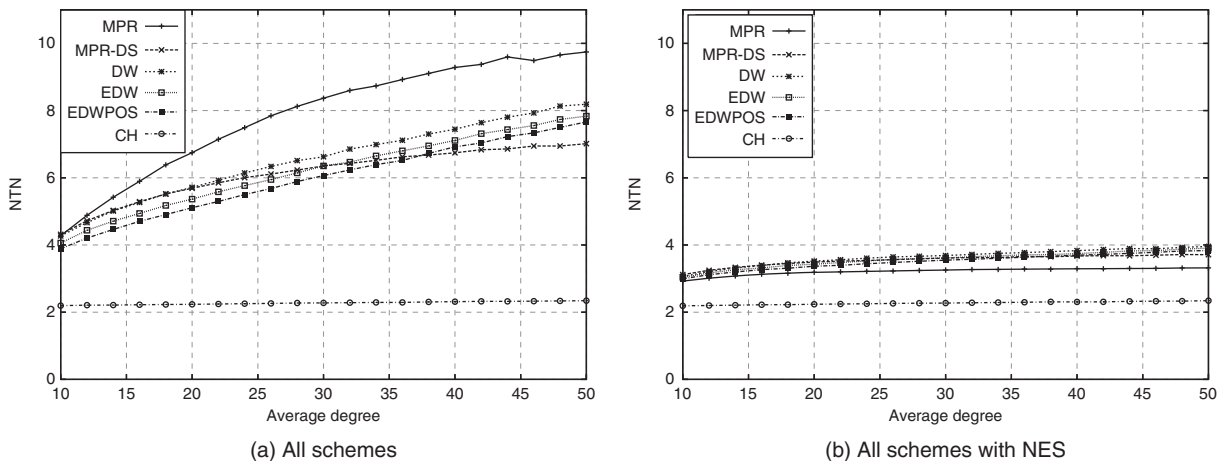

Figure 12: NTN versus average degree

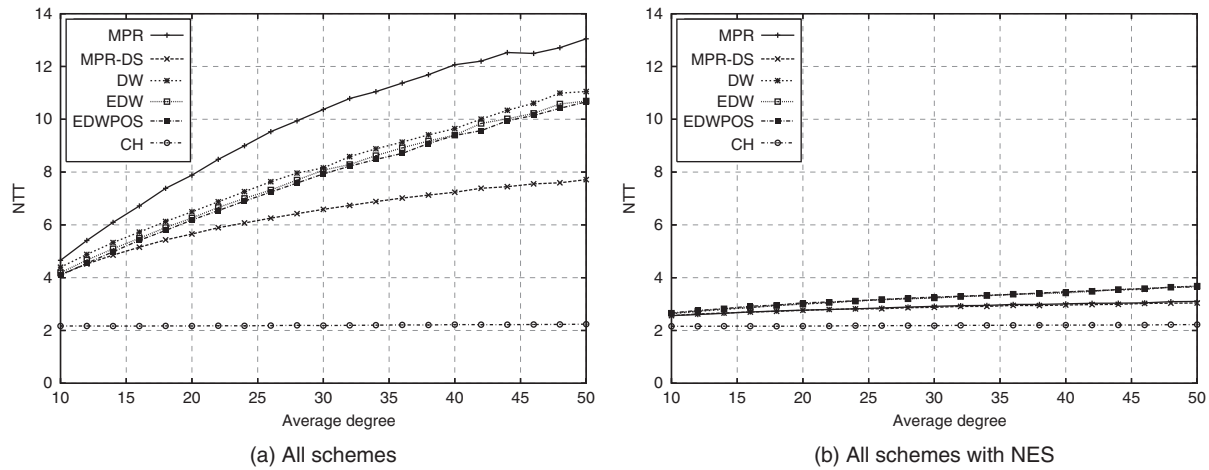

Figure 13: NTT versus average degree

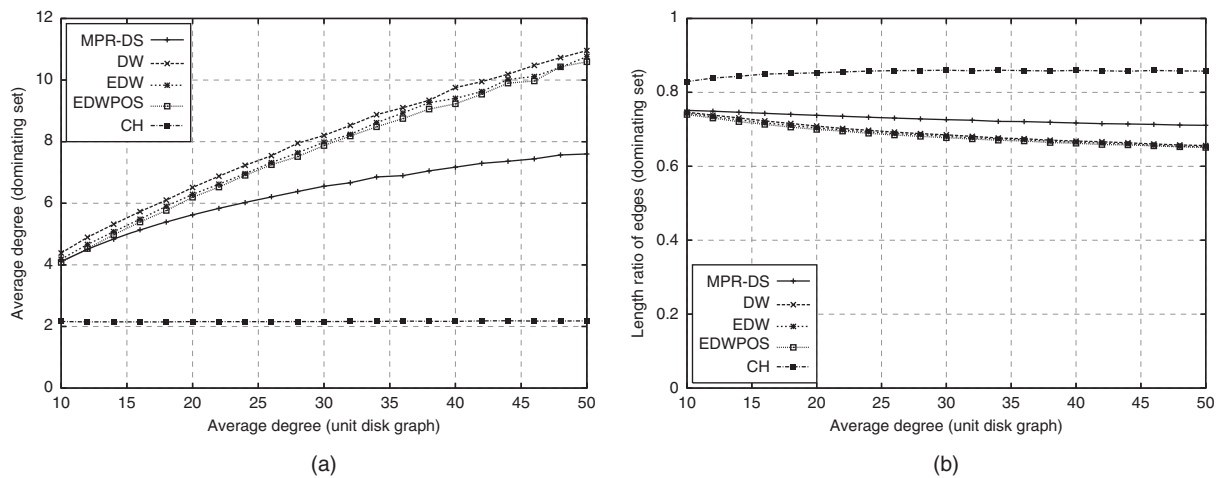

Figure 14: Comparison of the produced CDSs

stable and does not really depend on the degree of the unit disk graph. The four localized schemes obtain nearly the same results, while CH has higher values. This can be easily explained: in this heuristics; at each step, the node with the highest number of 'non-covered' neighbors is chosen, and we can expect this value to increase with the distance between the nodes.

CONCLUSION

From the variety of simulations studied, we can draw a number of conclusions. The first, and most important one, is about the neighbor elimination scheme. It enhances the performance of all the protocols as an added feature. In our simulation studies, it reduces the number of instances of re-broadcasting, as well as message redundancy of both transmitting and non-transmitting nodes, and provides more enhancements in dense networks. Even in sparse networks, enhancements are sufficiently

high to be noticeable. The MPR protocol seems to benefit the most from the addition of the NES.

Among all the examined localized schemes, EDWPOS+NES appears to require the fewest number of retransmissions. If we restrict consideration to topological information, the enhanced definition EDW + NES still is the one with the lower retransmission count, but the advantage over the two other NES based schemes is not major. The MPR-DS+NES scheme seems equivalent to other CDS schemes, but requires a third round of HELLO messages, and therefore is inferior in dynamic networks. It thus appears that pure dominating set-based approaches are winning methods overall, remaining competitive in all network scenarios.

All algorithms depend on the density of the network. In sparse networks, more nodes need to rebroadcast to reach all the nodes in the network. As the density increases, proportionally fewer nodes need to rebroadcast. As the density of the network increases, so does the number of times

each node, transmitting or non-transmitting, receives the same message. The transmitting nodes receive more copies of the same message than non-transmitting nodes for all d values.

For future research related to this chapter, a more realistic environment could be considered. Indeed, we evaluated the performance of the selected schemes and the constructive effect of adding an NES, and we assumed an ideal MAC layer. But in real networks, as the network density increases, heavier contention and collision increase the probability of packet loss. Future study could thus evaluate the performance of the broadcasting protocols under contention, collision, and other network conditions.

Another issue in wireless ad hoc and sensor networks is the presence of node mobility and different transmission radii. Maintenance of connected dominating structure in the presence of moving nodes is a significant operation that may involve a significant amount of message traffic. Different transmission ranges of the mobile nodes or a hidden terminal problem might cause unidirectional links. The performance evaluation of the broadcasting protocols may provide new insights by considering the influence of these factors.

More work still needs to be done about the evaluation of energy consumption when energy spent upon reception of packets is taken into account. Indeed, it has been pointed out very recently that the reception of a message can be more expensive than its transmission (Lu et al. 2005). In this case, the number of receiving nodes becomes a factor of prime importance, even more than the number of transmitting nodes: as the density increases, there are fewer transmissions but more receptions, and thus the energy consumption also increases until a threshold is reached, where the number of transmissions is sufficiently low to counterbalance the high number of receptions. This is different from what has been considered in previous studies and quite a new problem to solve.

GLOSSARY

Broadcasting: Sending a packet from a source node to all other nodes.

Dominating Set: A set of nodes such that every node either belongs to this set, or is a neighbor of a node that belongs to this set.

Positional Knowledge: The term used when a node knows the exact location of its neighbors.

Reliable Broadcasting Protocol: A broadcasting protocol that ensures delivery of the packet to every node connected to the source node, under ideal conditions.

Topological Knowledge: A term used when a node is only aware of links between its neighbors, but does not know their location.

INTRODUCTION

The recent advances in micro sensor technology and low-power analog/digital electronics have led to the development of distributed, wireless networks of sensor devices. Sensor networks of the future are envisioned to consist of hundreds of inexpensive nodes that can be readily deployed in physical environments to collect useful information (e.g., seismic, acoustic, medical, and surveillance data) in a robust and autonomous manner. A distributed sensor network is usually a self-organized system composed of a large number of sensor nodes that collaborate with one another to measure different parameters that may vary with time and space, and to send the corresponding data to a collector center for further processing.

Application domains are diverse and can encompass a variety of data types including acoustic, image, and various chemical and physical properties. These sensor nodes will perform significant signal processing, computation, and network self-configuration to achieve scalable, robust, and long-lived networks. Furthermore, because of power and transmission range limitations, data dissemination in sensor networks is typically carried out as a collective operation, in which sensors collaborate to get data from different parts of the sensor network to the information sinks (Akyildiz et al. 2002). The collaboration among different sensor nodes is mostly realized through multihop network architectures because of their energy-efficiency and scalability features (Shen, Srisathapornphat, and Jaikao 2001).

A major energy consumer in wireless sensor networks is radio communication. A comparison of the cost of computation to communication presented by Pottie and Kaiser (2000) reveals that 3000 instructions can be executed for the same cost as the transmission of one bit over 100 m. Energy conservation in such networks involves two dominant approaches to minimize communication overhead. The first is at the medium access control (MAC) and network layers, where nodes turn off their radios when they are not required for multihop communication.

The second is data reduction through in-network processing (also called data aggregation), where correlations in data are exploited to reduce the size of collected and transmitted data, and correspondingly communication cost. Because local computation is much cheaper than radio communication, supporting some in-network processing to reduce data within the network, and thus shifting the computation into the network, can provide significant energy savings.

Toward this direction several research works in the literature have discussed the problems of developing efficient joint routing and data management techniques, as well as application-specific data aggregation processes, to support efficient data monitoring and gathering approaches in sensor networks. Furthermore, several issues associated with the data aggregation process with the specific objective of meeting the task requirements (i.e., quality of service [QoS] constrained data monitoring and gathering) have also been recognized and considered recently. The rest of this chapter is structured as follows. We first present some performance metrics of interest for the design of efficient data monitoring and gathering methods, followed by a discussion of the related traffic and data correlation models. We then discuss several issues associated with the sensor node deployment patterns for the implementation of effective data monitoring. We also describe several data gathering approaches by classifying them into many diverse categories according to different features and design dimensions of the wireless sensor networks, and present some indicative associated protocols. Finally, we present a relative qualitative comparison of the different data gathering approaches, highlighting their respective merits, drawbacks, and performance.

PERFORMANCE METRICS

Before we describe and discuss the various data gathering and dissemination approaches, we first present some performance metrics of interest and their impacts on the

design of efficient and effective data monitoring and gathering methods. The sensor network should dynamically adapt to the system and topology changes; at the same time, it needs to balance the trade-offs among the various performance metrics. Following is a summary of the main performance metrics that need to be considered by the data monitoring and gathering approaches in sensor networks.

Delay/latency: For time-crucial applications, the sensor nodes are required to complete the data monitoring and gathering task within a predefined and strict latency; any data received out-of-date is considered useless. The definition of *delay* is application dependent; the *latency* might be defined as the time interval from the point when a query is sent out until proper information is received by an end user. Alternatively, it may be defined as the time required for some collected data to be transmitted back to the collection sites. In most cases, of practical interest are some statistics with respect to the delay (e.g., average delay, probability that delay is less than some given threshold), rather than single delay values.

Energy efficiency and network lifetime: The parameters used to evaluate the degree of energy efficiency include the average energy used to transmit a bit to/from the source to the collection center (J/bit), the total energy consumption/dissipation over an operation time period (J/unit time), and the ratio of the energy consumed to transmit the data payload to that consumed to transmit the overhead. Closely related to the energy efficiency is network lifetime. Depending on the application under consideration, the network lifetime can be defined as the time interval from the point that the sensor network starts its operation until: 1) the first node dies; 2) the sensing coverage falls below a prespecified threshold; 3) the number of active nodes is less than a prespecified threshold; or 4) loss of communication to the collection site by all sensor nodes occurs.

Accuracy: The precise definition of the accuracy is determined by the specific application. For example, if the sensor network is used to monitor environmental variables, the observed signal specifications such as temporal resolution, spatial resolution, and range accuracy are the accuracy parameters of concern. In target detection and classification applications, the accuracy may involve the missing-detection probability, false-alarm probability, and the average classification accuracy.

Sensing coverage: According to the deployment schemes, the sensing coverage can be divided into two categories: deterministic coverage and stochastic coverage. *Deterministic coverage* means that the placement is predetermined so that each node can be deployed at a specific position. The predefined deployment patterns could be uniform in different areas of the sensor field, or can be weighted to compensate for the more critically monitored areas. The *stochastic coverage* refers to the scenario in which the sensor field is covered with sensors randomly distributed throughout the environment. The sensing coverage relies not only on the appropriate placement of the nodes but also on their sensing capabilities.

Throughput: Because the bandwidth in sensor networks is limited and high node density may produce large amounts of data, the end-to-end transmission throughput needs to be maximized, besides providing fairness and low

complexity of implementation. In some applications such as forest fire or nuclear power plant monitoring (Mladineo and Knezic 2000; Lin, Wang, and Sun 2004), the information disseminated may increase abruptly when an emergency event occurs, and as a result peak throughput provided should satisfy the requirements under this scenario.

Additional parameters: Some additional simplified and specific metrics, such as bit-hop metric (Pattam, Krishnamachari, and Govindan 2004), the ratio of payload data to overhead of packets, and the probability of buffer overflow have also been used to indicate the degree of energy efficiency. Lindsey, Raghavendra, and Sivalingam (2002) proposed and used the product of the energy and delay (i.e., energy*delay) as a potential metric to capture the system performance on balancing the energy and delay cost for data gathering in sensor networks. Alternatively, weighted cost functions can be used to balance the trade-offs of the various performance metrics. The cost function can be defined as the sum of products of the weights and the corresponding performance elements (e.g., delay, energy efficiency, accuracy, Zhu, Papavassiliou, and Yang 2006), where the weights can be adjusted according to the end-user demands and requirements.

TRAFFIC MODELING AND DATA CORRELATION

Sensor networks are typically more application specific than traditional communication networks that are designed to accommodate various types of traffic and applications. As a result, closely related to the data monitoring and gathering process for different applications and scenarios are the corresponding traffic models and data correlation models.

Traffic Models

Depending on the patterns of the measurement and information to be monitored and transmitted, the traffic can generally be divided into three main categories: deterministic traffic, event-driven or threshold-sensitive traffic, and response-to-inquiry traffic. For the first type, there is a steady traffic flow between the source node and the sink. In such cases, sensors usually generate deterministic and/or periodic traffic, in which each node transmits its data once every specific time interval. The event-driven or threshold-based mode corresponds to cases where transmission of information is triggered by an event (e.g., a monitored variable exceeds some threshold; the change of an attribute value exceeds some predefined threshold, etc.). The sensor networks that aim at object detection or system monitoring (e.g., road traffic monitoring, forest fire monitoring, etc.) usually present this type of traffic. The third class, response-to-inquiry traffic, corresponds to cases where the sensors respond to inquiries dispensed by an end user or observer, which may be targeted to a specific set of sensors and/or for a specific time interval.

In general, various applications may involve more than one traffic modes. For example, in a seismic monitoring sensor network, the observation value will be periodically sent back to the collection site to record and accumulate

data at the normal operation state for further analysis and processing; however, when the seismic intensity (vibration amplitude) measured exceeds a specific threshold, the observation will be transmitted to the sink immediately and the end users may further issue inquiry-based traffic. The different traffic and load conditions in the network may impact the performance of the data gathering approach. For instance, the ad hoc response-to-inquiry traffic results in two-way communication that involves the dissemination of both the inquiries and the collected data, whereas the other two modes mainly generate one-way communication flows. The data dissemination and gathering strategies should be selected taking into account the different traffic models. For deterministic traffic, the data gathering strategy can be optimized based on certain known patterns, whereas in principle the data gathering strategy should be able to adapt to the burst change of the traffic, in order to accommodate other traffic modes as well.

Data Correlation Modeling

Unlike traditional wireless cellular networks, in which the communication is person-to-person and the contents of conversations are irrelative to one another, in sensor networks the data in the neighboring nodes are considered highly correlated because the observed objects in the same geographical location are usually strongly correlated. Under this assumption, the data processing and aggregation might utilize the spatial correlation of local nodes and dramatically decrease the amount of information to be transmitted. Estimation of the data correlation properties based on the previous and current collected data can be used to locally optimize the data compression and aggregation in the subsequent data gathering phases. Furthermore, utilizing the appropriate spatial correlation models to generate synthetic data based on the availability of only a small amount of experimental data inputs allows for efficient and accurate testing and evaluation of the corresponding data monitoring and gathering approaches (Jindal and Psounis 2004).

With respect to the signals emitted from certain sources, it is usually assumed that the signal magnitude of the event's effect at a distance d from the source is proportional to $1/d^\alpha$, where α is the propagation parameter. The value of α depends on the type of sensing event (e.g., seismic vibration, sound, light, infrared signal, etc.) and the medium in which the signals travel/propagate (e.g., ground, air, water). If the observation has multiple sources, the signal event arriving at a node is usually obtained as some function of the multiple events' effect.

In principle, the readings at each sensor can be regarded as samples of a random variable. Therefore, statistical joint moments of two random variables can be used to summarize the corresponding correlation properties. Assuming that the observations at two nodes are represented by random variables X and Y , respectively, then the ij -th joint moment of X and Y is represented by $E(X^i Y^j)$. For $i = j = 1$, the resulting moment $E(XY)$ is called the correlation of X and Y , whereas the covariance of X and Y is defined as: $COV(X, Y) = E[(X - E(X))(Y - E(Y))]$, where $E[X]$ and $E[Y]$ denote the expected values of random

variables X and Y , respectively. Both of these statistics are among the most commonly used to characterize the correlation between two observation sets. For sensors using n -bit A/D converters, based on the fact that a reading can be represented as one of the 2^n possible values whereas the difference of the readings among nearby nodes may be represented by fewer than n bits, Chou, Petrovic, and Ramchandran (2003) proposed a differential encoding method that allows nodes to transmit fewer bits for each reading. A linear model is used to estimate the correlation between two sample data of two nodes and to further determine the number of bits with which to ask the sensors to encode their values. According to this model, the optimal scaling factor that can provide best estimation between two known reading sets X and Y was found to be $E[XY]/E[Y^2]$.

In a more information-theoretic based approach, the correlation among observations at different sensors can also be characterized by the joint entropy of multiple sources (Pattam, Krishnamachari, and Govindan 2004). Given knowledge of some data from other sensors, the conditional entropy of the quantized data of one sensor can be computed. It is expected that the conditional entropy decreases when nodes get closer. Thus, using entropy coding, sensors can compress their data and transmit at a rate equal to the corresponding conditional entropy.

SENSOR DEPLOYMENT FOR DATA MONITORING AND GATHERING

The overall purpose of an efficient data monitoring and gathering methodology is to provide accurate and timely information, and at the same time extend the network operation lifetime for as long as possible. The optimal data gathering strategy depends on the density of nodes, position of sink, task requirements, and amount of correlation among the sources of the data. Therefore, to develop effective data monitoring and gathering strategies, we first need to develop an appropriate deployment scheme, which includes determining the number of nodes, density, types of sensor nodes, and how to deploy the nodes (e.g., deterministic or random), to achieve the required objectives, such as sensing coverage, fault tolerance, measurement accuracy, and so forth.

The placement of sensors has significant effects on many factors associated with the data monitoring and gathering in sensor networks, such as the desired accuracy, temporal and spatial resolution, evolution of the information to be gathered and disseminated, connectivity, efficient routing, and fault tolerance. The deployment planning process involves a detailed analysis of the environmental map and related data to determine the most appropriate placement of sensor nodes and maximize the sensor field coverage. In general, the sensing coverage reflects how well an area is monitored or tracked by sensors. Because of the inherent uncertainty associated with the processes of monitoring and sensing, probabilistic modeling of sensor coverage is desired. After the sensors are deployed according to a predetermined pattern, the locations of the nodes can be adjusted or additional sensor nodes may be placed to

Figure 1: Predetermined mesh topology sensor network

maintain the required sensor coverage and/or the desired network connectivity as the sensor network evolves.

Various deployment approaches that may range from deterministic to random have been considered by taking into account different constraints and situations. In Figure 1, a predetermined mesh topology is presented; Figure 2 depicts the topology of a randomly deployed network. Specifically, for deterministic deployment, each node is placed at a specific position (manually or using robots) to maximize the sensor coverage. This method is suitable for cases where the sensors are static or fixed and sufficient knowledge of the environment is available for precalculation of the optimal sensor positions. This case is similar to the art gallery problem (AGP; O'Rourke 1987), and usually the suboptimum solution can be obtained by heuristics methods. For example, Chakrabarty et al. (2002) have developed approaches for deployment in two- and three-dimensional grids by formulating the node placement problem as combinatorial optimization and coding theory problems, and solving them using integer linear programming.

Although this kind of well-controlled node placement can provide good coverage for a given scenario, it is

infeasible in many situations because the sensors may be deployed in unfriendly areas or the associated cost could be quite high for deterministic placement of a large number of nodes. Therefore, the alternative option—random deployment of sensor nodes, such as throwing sensor nodes from air vehicles into the target area—is often more practical and desirable. In this case, the sensor field is covered with sensors randomly distributed in the environment, the aforementioned stochastic coverage; Meguerdichian et al. (2001) proposed a centralized polynomial time algorithm for the computation of worst-case and best-case coverage for random deployment using Voronoi diagram and graph search algorithms. In order to achieve energy efficiency, several algorithms have been proposed to address how to adaptively place sensors into the sleep mode while still maintaining full coverage of the sensing fields (see, e.g., Cerpa and Estrin 2002; Huang and Tseng 2003).

In some situations, it is expected that only very limited prior knowledge of the possible targets—or even no knowledge of the corresponding terrain—would be available. In this case, the single-step deployment may produce inferior coverage because of the lack of environmental information. One alternative method is to deploy sensors

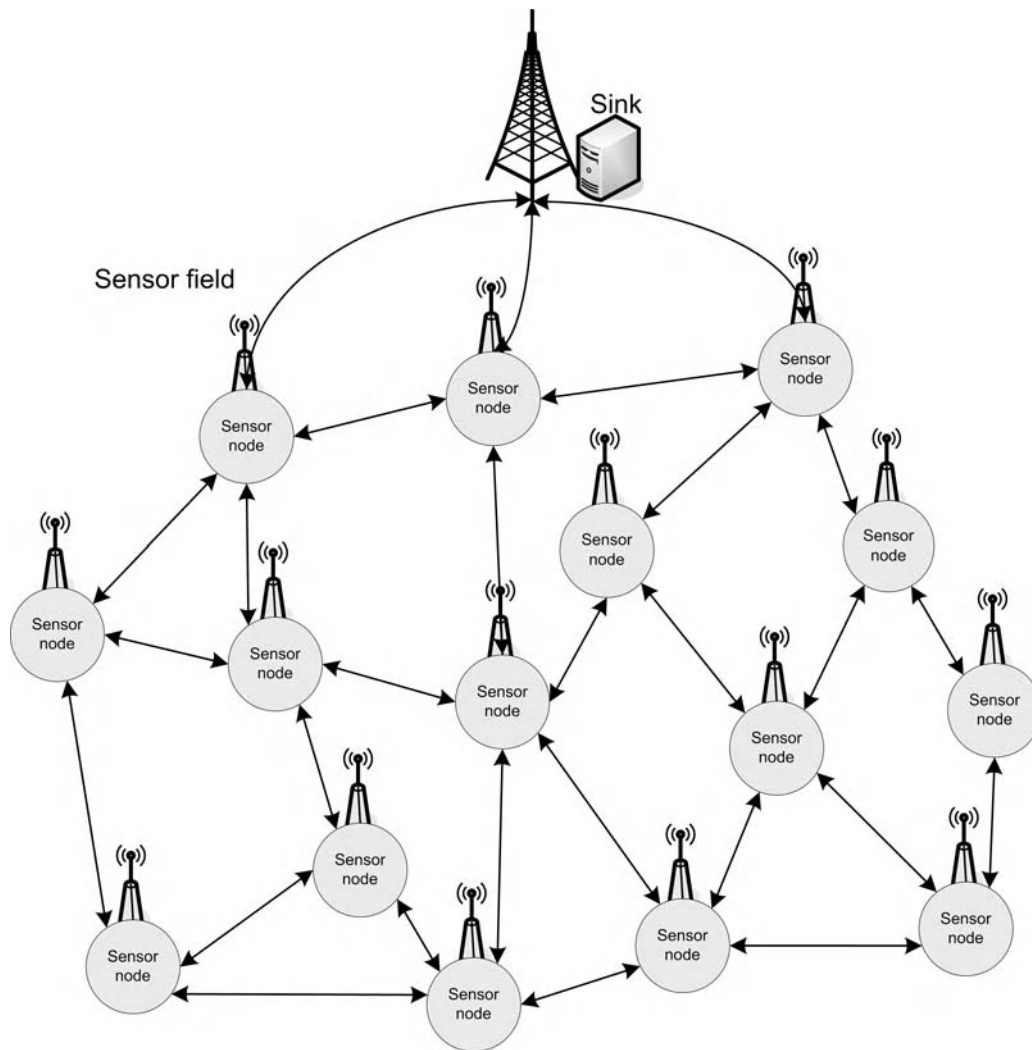

Figure 2: Randomly deployed sensor network

sequentially (i.e., to scatter a subset of the sensors at each step) and the information cumulated from previous deployed sensor nodes will be used to determine the further deployment steps. Clouqueur et al. (2002) developed an incremental deployment approach of sensor nodes for target detection purposes. Only subsets of the available nodes are deployed in each step until the minimum exposure or probability of target detection is achieved. Additional methods have been proposed to determine the insufficiently covered regions based on different criteria. For instance, Huang and Tseng (2003) proposed polynomial-time algorithms, in terms of the number of sensors, to determine whether every point in the sensor field is covered by at least k sensors.

It should be noted here that a large number of uncertainties may occur in the sensor deployment process. For instance, when dispensing sensors from air vehicles, the actual landing position is affected by many elements, including the trace of air vehicles, the wind, the terrain conditions, and other obstacles such as trees and buildings. Recently, Zou and Chakrabarty (2004) proposed a new approach to address the uncertainty problem. The proposed approach aims at optimizing the number of sensors and

determining their placement in order to maximize the average desired coverage, as well as the coverage of the most vulnerable regions in the sensor field. Even for deterministic deployment, the expected sensor coverage and the actual results may differ because of the change of environment as the network evolves. Therefore, as previously mentioned, further adjustment may be required after the initial deterministic or random deployment. This could be achieved either by moving the deployed nodes to their desired location or by placing supplementary sensor nodes to cover the blind spots. Because the position of mobile nodes is easy to adjust, they are usually used to implement self-deployment or to provide enhanced flexibility. Toward this direction, Wang, Cao, and La Porta (2004) have designed distributed movement-assisted self-deployment protocols for mobile sensors, based on the principle of moving sensors from densely deployed areas to sparsely deployed areas.

Another important design challenge of a sensor network is the issue of self-organization, which refers to the ability of the system to achieve the necessary organizational structures without requiring human intervention. Self-organization is a critical attribute needed to achieve the

wide use and applicability of distributed sensor networks. Consequently, once the sensors are deployed, they have to form networks in an autonomous manner, using self-organizing procedures to discover their neighbors and acquire their location. In addition, because of the dynamic nature of the network and the energy constraints of the sensors, fault tolerance and self-healing are required for an operation that will be left unattended for an extended time to be feasible. Sensors may get disconnected from the network because of their battery depletion, and new sensors may be deployed to maintain the connectivity and the environmental coverage of the network. Therefore, self-organization procedures (e.g., self-management, self-healing) must be provided so that the network can work in a robust and autonomous manner. For instance, Sohrabi et al. (2000) have presented a series of protocols for establishing and maintaining connectivity in wireless sensor networks: the self-organizing medium access control for sensor networks (SMACS), eavesdrop and register (EAR), and sequential assignment routing (SAR) protocols. Gupta, Das, and Gu (2003) also addressed the self-organization issue and developed protocols for sensor networks for efficient query execution. Moreover, most of the data gathering approaches presented later in the chapter include methods for handling sensor node failures and insertions.

As mentioned earlier, one of the key features of self-organization is localization. Location awareness of the sensors is crucial for the operation of a large-scale network, enabling the intelligent selection of appropriate devices and supporting useful coordination among them. In addition, localization can offer a complementary way to reduce energy consumption in multihop wireless sensor networks (e.g., by improving routing; Bulusu, Heidemann, and Estrin 2000). In many cases, sensors are assumed to have knowledge of their location based on global positioning system (GPS) coordinates. In reality, however, this solution may be not applicable to all sensors because of cost, antenna size, and power consumption constraints; therefore, several localization techniques have been proposed in the literature. Most of these consider the case where a few sensor nodes (known as beacon or anchor nodes) of the network have a priori knowledge of their positions, either from a GPS device or by manual configuration, whereas the rest of the network sensors acquire their location by calculating their distance from the anchor nodes based on the packets received and the signal strength (Langendoen and Reijers 2003). Depending on the number of beacons used, as well as the algorithms deployed for the calculation of the distance and the angle/direction, a different grade of location accuracy can be achieved.

Experimental Sensor Network Deployment

Sensor networks can greatly improve environment monitoring for many civil and military applications, such as target detection and classification, precision agriculture, habitat monitoring, or patient monitoring. One of the experimental wireless sensor network pioneers is the Great Duck Island project (<http://www.greatduckisland.net>). In August 2002, researchers from UC-Berkeley/Intel Research Laboratory deployed a mote-based tiered sensor

network on Great Duck Island, Maine, to monitor the behavior of storm petrel. Furthermore, in December 2004, the OSU DARPA-NEST team completed the first demonstrations and experiments of ExScal (www.cast.cse.ohio-state.edu/exscal/). The ExScal project deploys about 1000 sensor nodes and 200 backbone nodes, making it the largest wireless network assembled to date. The purpose of the development of ExScal is for the detection and classification of multiple intruders types over an extended perimeter. Other habitat-monitoring examples include the PODS Project (<http://www.pods.hawaii.edu/>), which is used to remotely monitor the rare species of plants in Hawaii for long-term study, and ZebraNet (<http://www.princeton.edu/~mrm/zebranet.html>), which is used to study zebra behaviors such as long-range migration, interspecies interactions, and nocturnal behavior. The Sensor Web (<http://sensorwebs.jpl.nasa.gov/>) measures light levels, air temperature, humidity, soil temperature, and soil moisture, and the collected data are used to study the effects of microclimate on plant growth. Recently, Intel also deployed a sensor network with sixty-five nodes at a vineyard in British Columbia, Canada (http://www.intel.com/research/vert_agri_vineyard.htm). Wine grapes are highly sensitive to temperature; therefore, real-time temperature; data from the motes (sensor nodes developed by UC-Berkeley) can identify which vines are most likely to need frost-control measures, whereas the cumulative temperature data can help the grower choose the best moment to pick the grapes. Finally, with regard to patient monitoring, several experimental sensor networks have been deployed. Researchers from Harvard University have developed a scalable software infrastructure for wireless medical devices, called CodeBlue (<http://www.eecs.harvard.edu/~mdw/proj/codeblue/>). CodeBlue is designed to provide routing, naming, discovery, and security for wireless medical sensors, personal digital assistants (PDAs), personal computers (PCs) and other devices that may be used to monitor and treat patients in a range of medical settings. The sensor nodes that are used are called VitalDust (Vital Sign Sensors) and collect heart rate, oxygen saturation, and EKG data, and relay it over a short-range (100m) wireless network to any number of receiving devices, including PDAs, laptops, or ambulance-based terminals. Moreover, the ubiquitous monitoring environment for wearable and implantable sensors (UbiMon) project aims at addressing general issues related to using wearable and implantable sensors for distributed mobile monitoring (<http://www.ubimon.org/>). The aforementioned experimental sensor networks can provide empirical data sets for further study and optimization of the data sensor networks.

DATA GATHERING STRATEGIES

The simplest possible strategy to send data from the sensor nodes to a base station is called *raw data gathering* and consists of direct transmission of the information from all sensors to the sink (Heinzelman, Chandrakasan, and Balakrishnan 2000). If the base station is far away from the sensors, a huge amount of transmit power is required, which would lead to a quick depletion of the energy recourses of every sensor and consequently reduce the

network's lifetime. Although the raw data gathering approach could in principle provide a nearly optimal solution in cases where the sink is close to the nodes, in most cases, even for moderate-sized sensor networks, this approach is considered energy inefficient. To prolong the network's lifetime, data reduction is necessary; this is achieved mainly through in-network processing. Because the observed objects in the physical world are usually highly correlated, sensors that are deployed close to one another are expected to collect similar information about their environment, and thus data aggregation methods can be utilized to improve the overall data gathering operation.

Data gathering approaches can be classified into many diverse categories according to different features and design dimensions of the wireless sensor networks and associated protocols. More specifically, given the network's structure and organization, data gathering approaches can be divided into two main categories: hierarchical and nonhierarchical protocols. The hierarchical approaches are further divided into the cluster-based, chain-based, and aggregation tree constructive protocols. Clustering is the partitioning of a data set into subsets, so that the data in each subset share some common trait. In the case of wireless sensor networks, nodes are organized into groups, called *clusters*, and a node is elected to act as the group leader (called the *cluster head*). Clusters can also be used to form different layers of a hierarchy. The member nodes of each cluster send their data to the cluster head, which is responsible for sending the collected data either to a higher layer cluster head or directly to the sink. Chain-based protocols construct a chain connecting all nodes, thus reducing the total distance of data transmission. Nodes send their data to their neighbor node in the chain, and each node is responsible for forwarding its neighbor's data, possibly along with its own data. At each round, only one sensor transmits the total data packet to the sink. The third category of the hierarchical approaches includes protocols that construct trees rooted at the sink and spanning the whole network. In these schemes, each node sends its data to its parent in the tree, and the parent node fuses it with its own readings and passes it to its parent one layer above until the aggregated packets reach the final destination node. On the other hand, the nonhierarchical approaches disseminate the data throughout the whole network in a flat manner, without involving any physical or logical hierarchical structure (e.g., through flooding).

One of the basic and critical operational processes in sensor networks, that is closely related to the data gathering is the routing process. Therefore, a large number of strategies that have been proposed in the literature perform the gathering of data generated in the network along with the corresponding routing decisions made, in order to optimize the overall process. On the other hand, there is a class of protocols for data gathering that aims to be routing independent. The objective of this class of protocols is to provide a more generalized and flexible data aggregation and gathering framework that achieves energy efficiency in a way that is independent of and complementary to the routing protocol.

An additional dimension encountered in wireless sensor networks—different from most of other wireless and

personal networks—refers to the nature and the different kinds of data that are transmitted. Although a large number of approaches send the collected data in their genuine form, it is possible that alternative approaches can be used to send encoded data to reduce the amount of data transmitted in every gathering round. This approach also constitutes a form of aggregation or, more precisely, fusion, and the corresponding techniques are known as distributed data compression techniques. They mainly reduce the amount of data transmitted by exploiting the spatial correlations that exist among different data packets.

A separate class of data aggregation methods can be created by several approaches that take advantage of the spatial correlations between the sensors' readings, in a rather different way than the ones mentioned above, by selecting only a subset of sensors to perform data gathering. More precisely, these approaches do not perform actual data aggregation but instead at each gathering round select subsets of nodes to report their readings. Neighborhood nodes are expected to collect analogous information; therefore, only one is active at each round and sends its gathered data to the sink. The other nodes move into idle or sleep mode to save their energy resources. These methods are comparable to the MAC approaches in which sensor nodes turn off their radios to achieve energy efficiency.

Furthermore, it should be noted that in most common scenarios in sensor networks, individual sensors are deployed in an area and are usually immobile, forming a wireless fixed network. However, there are some cases (e.g., for tracking applications) where the sensors can move either by outside force or by their corresponding mobility component. Therefore, for these cases, mobility presents an additional challenge that may affect the operation and effectiveness of the data monitoring and gathering process.

In wireless sensor networks, the sensors either continuously sense their environment and send their data to the sink in a periodic manner or gather data in an event-driven way, in which sensors report their readings only if an event has occurred (e.g., a value threshold has been exceeded). However, in some cases, users or applications may request data on demand by posing different types of queries to the sink. Therefore, the methodology and frequency of the data collection process also pose different and interesting design challenges in wireless sensor networks.

The aforementioned categorizations and classes of data monitoring and gathering approaches do not constitute mutually exclusive groups, and, as a result, one methodology may belong to more than one class. Naturally hybrid solutions are required to consider and balance the corresponding trade-offs, depending on the overall objective of the developed strategy. In the following section, we present a more detailed description of each one of these classes, by providing representative protocols and describing the operation and functionality of these approaches.

Hierarchical Protocols

Cluster-Based Protocols

As mentioned before, in cluster-based approaches clusters are formed with one leader (cluster head) at each cluster. The cluster head is engaged in collecting all the

Figure 3: Cluster-based data gathering approach

data from the members of its cluster, performing some sort of data aggregation in order to reduce the data size, and forwarding it either to a higher-layer cluster head or directly to the sink. The corresponding cluster-based formation is illustrated in Figure 3.

Heinzelman, Chandrakasan, and Balakrishnan (2000) presented the low-energy adaptive clustering hierarchy (LEACH) protocol, which is considered one of the most representative cluster-based protocols. In the implementation of LEACH, sensors are organized into clusters with one node acting as leader at each round. The member nodes of each cluster send their data to their cluster head, which in turn performs local data fusion to compress the amount of data to be sent, and at the end of each round sends the corresponding data to the sink. The cluster head sensors, which at each round transmit to the sink, consume significantly larger amount of energy, especially when compared to the other types of nodes. In order not to drain the batteries of these sensors, randomized rotation of the high-energy cluster-head role is utilized. The clusters are reconstructed every round and every time a new sensor is elected cluster head in a random way. In a centralized version of LEACH, called LEACH-C (Heinzelman 2000), the cluster formation is done at the beginning of each round using a centralized algorithm initiated by the base station. Although this version of the protocol performs better than LEACH, the associated energy cost for the cluster formation is higher and knowledge of the network topology is required for the cluster formation phase.

Another approach suggests an enhanced version of the LEACH algorithm, namely E-LEACH (Pham, Kim, and Moh 2004). This implementation contains four phases: a) advertisement, b) cluster setup, c) schedule creation, and d) data transmission. The first three phases are identical to the original LEACH algorithm, whereas in the last phase all cluster heads, after receiving the data from their cluster members, form a chain using a greedy algorithm starting from the cluster head that is farthest from the sink and transmit their data along the chain.

Choi, Shah, and Das (2004) proposed a two-phase clustering scheme to improve energy efficiency. In the first phase, the sensor network is partitioned into clusters, each with a cluster head, and sensors join the nearest cluster head by forming a direct link to it. During the second phase, cluster members are required to search for a cluster member neighbor who is closer than the cluster head, and form a data relay link to it. Each time a member node has data to transmit, it either uses the direct link or the data relay link to send its data, depending on the delay constraint to be met. The data relay point aggregates its sensed data and received ones, and then forwards the aggregated data to its data relay point or the cluster head. When all data have been collected at the cluster head, it is forwarded to the sink. In this way, further improvements in energy savings and distribution of the cluster head's workloads can be achieved.

Dasgupta, Kalpakis, and Namjoshi (2003) proposed an alternative cluster-based approach for data gathering. The network is partitioned into clusters, called *super sensors*,

which make use of a greedy clustering algorithm that selects the farthest sensor node i from the sink and forms a cluster that includes node i and its $(c-1)$ nearest neighbors, where c is a constant. The process continues until all sensors have become members of a cluster. For every super sensor, a maximum data gathering lifetime schedule is computed using a greedy clustering-based maximum lifetime data aggregation (CMLDA) heuristic. A data gathering schedule specifies how the data packets from all the sensors are collected and transmitted to the sink. Based on each schedule computed, aggregation trees are constructed for the sensors.

Chain-Based Protocols

Another class of hierarchical protocols for data gathering is the chain-based protocols. Chain-based protocols construct a chain that connects all nodes, thereby reducing the distance of total data transmission and decreasing the energy dissipation per round. A representative chain-based topology is shown in Figure 4. Among the simplest chain-based protocols presented in the literature is the linear-chain scheme. A linear chain connects all nodes within the network and data is transmitted from one end of the chain to the other. Each node attaches its own data to the received data to form a larger packet and sends it to the next node. To conserve energy, each node maintains the same size of header.

Among the most representative examples of a linear-chain protocol is the power-efficient gathering in sensor information systems (PEGASIS) protocol (Lindsey, Raghavendra, and Sivalingam 2002), in which each node communicates only with its closer neighbor and takes turns transmitting to the sink. The nodes are organized to form a chain, which can either be computed in a centralized manner by the sink and broadcast to all nodes

or accomplished by the sensor nodes themselves using a greedy algorithm. At each round, a node receives a data packet from its neighbor in the chain, fuses it with its own data (thus generating a single packet of the same length) and transmits it to its other neighbor in the chain. At each round, only one node is assigned to transmit the total data packet to the sink. Each time a different node is selected in order to increase the network's lifetime. The drawback to the linear-chain schemes is the large delay from data sensing to data transmission to the base station, and therefore enhanced chain-based schemes for data gathering have been proposed.

A chain-based protocol for data broadcasting and data gathering was also the subject of a similar study presented by Du, Wu, and Zhou (2003), which is suitable especially in cases of sparse sensor networks. The authors divided the network into regions based on a center node. At each region, the linear-chain scheme is employed to gather the data of the sensors within the region at the center node. The center node can either combine the collected data using an aggregation function or simply relay the separate packets to the sink. The multichain scheme proposed constructs the subchains through a sequence of insertions.

Lindsey, Raghavendra, and Sivalingam (2002) also presented a binary combining scheme using code division multiple access (CDMA) in which it is possible for node pairs to communicate using different codes, thereby avoiding radio interference. Data are combined using pairs of nodes at each level, which results in a hierarchy of $\lceil \log N \rceil$ levels, where N is the total number of sensors in the network and $\lceil \log N \rceil$ represents the least integer greater than $\log N$. For data gathering, each node at a given level transmits to its neighbor. However, nodes that receive at each level, are the only ones that are active in the next level.

Figure 4: Chain-based data gathering approach

At the top level only one node is active and is responsible for transmitting the total packet to the base station. The nodes perform data fusion at each level, except for the end nodes. By allowing nodes to transmit simultaneously, the delay cost is reduced in comparison with the simple linear-chain scheme. However, using different codes for the communication of the sensors may not be applicable, because the CDMA-capable nodes are expensive. Thus, Lindsey, Raghavendra, and Sivalingam (2002) presented a chain-based three-level scheme without using CDMA. To allow simultaneous transmissions with minimum interference, the sensors of the network are divided in G groups (where G is a random integer and $G = 10$ is considered a near optimal choice). Within each group, the linear-chain scheme is used for G simultaneous transmissions.

Tree-Constructive Protocols

In these schemes, a rooting tree is constructed that spans the whole network. The sink initiates the process, and, at each step, new sensors join the tree until all nodes become members of the tree, either as internal nodes or leaves. The data gathering is performed along with the rooting; each node sends its data to its parent in the tree until the packets reach the destination node (i.e., the sink). Packets can also be aggregated in their way up to the root to conserve energy. Figure 5 presents the resulting topology of a typical aggregation tree-based protocol.

Thepvilojanapong, Tobe, and Sezaki (2005) suggested the efficient data gathering (EDGE) protocol, which is

basically a tree-constructing algorithm for data gathering. The tree is constructed as follows: the root initiates the tree construction by broadcasting a child request (CRQ) packet. Each node that is not a member of the tree collects a number of parent candidates, which are saved at a parent candidate (PC) table, and chooses one according to some metrics (e.g., the response time that signifies their distance). Then it sends a child reply (CPR) packet to the selected parent, and the parent responds by sending a child acceptance (CAC) packet. Specific joining and leaving procedures are provided by the protocol to handle the dynamic nature of sensor networks. If there is node failure, the tree is reconstructed. When the sink requests data or the nodes have data to send, the data gathering is performed using the gathering tree. Each node forwards its own data and all of the received data to its parent, until all the data are collected at the sink. If a node is not attached to the tree, it buffers the data and sends it later.

In a similar study, Tan and Körpeo (2003) proposed another tree-constructive algorithm, namely the power-efficient data gathering and aggregation protocol (PEDAP). The PEDAP computes a minimum spanning tree over the sensor network where the costs of the edges are proportional to the transmission costs. Each sensor node belonging to the tree aggregates (or fuses) the data provided by its children with its own, and transmits one single packet to its parent until it reaches the root of the tree (i.e., the sink). Prim's algorithm is used to compute the minimum spanning tree, and it is initiated

Figure 5: Tree-constructive data gathering approach

every k rounds to adapt to the given state of the network. Parameter k is configurable and presents a trade-off between complexity and accuracy.

Non-Hierarchical Protocols

Flooding is considered one of the most well-known non-hierarchical protocols in which the information is disseminated to the entire sensor network. Whenever a node has data to send, a copy is sent to all its neighbors. Likewise, whenever a node receives a data packet, it makes a copy and forwards it to its neighbors, except the neighbor from which it originally received the data. The use of flooding for data gathering is considered energy inefficient because a significantly large number of redundant data packets inundate the network and sensors consume their energy to handle these packets. Therefore, this approach is rarely used for data gathering and is useful only for very specific applications. Gossiping, (Heinzelman, Kulik, and Balakrishnan et al. 1999) is an enhancement of the flooding approach used to partially overcome the associated energy inefficiency problem. In gossiping, sensors do not forward the data packet to all of their neighbors but randomly select one to send the packet to. In that way, fewer copies of data packets are made and less traffic is generated in the network; as a result, less energy is depleted in every node.

The non-hierarchical approaches also include the directed diffusion proposed by Intanagonwiwat, Govindan, and Estrin (2000). This scheme is data centric—as data generated by a sensor node are named by attribute value pairs. The base station or any other node requests named data by sending interests, and data matching the interest are then drawn down toward that node. Each time a node senses data, the data are disseminated throughout the sensor network. This dissemination sets up gradients within the network, and, if interests fit gradients, paths of information flow from the nodes to the one that requested the data (usually the sink). The sensor network, in particular the sink, reinforces a small number of these paths in order to “draw down” higher quality data. To reduce the communication costs and the energy that is dissipated, data are aggregated on the way to the sink.

Routing-Independent and Probabilistic Methods

The data gathering approaches discussed in the preceding subsection are to a large extent dependent on the routing decision. In this section, different approaches that are routing independent and use probabilistic methods for performing data aggregation are presented. The corresponding aggregation strategies can be implemented at every individual node in a distributed fashion and are in principle complementary to the respective routing protocol used.

Zhu, Papavassiliou, and Yang (2006) presented a novel approach called QoS-constrained data aggregation and processing (Q-DAP), in which the application QoS requirements are taken into account to determine when and where to perform the aggregation function. Each intermediate sensor node determines independently whether or not to perform data aggregation randomly with some

specific probability that is precalculated according to the resource conditions and the specific task requirements. One of the main principles of the proposed scheme is that the network does not need to be formed into clusters to perform the data aggregation, whereas the task QoS requirements are taken into account to determine when and where to perform the aggregation in a distributed fashion, based on the availability of local information only. Upon receiving the data packets, the intermediate nodes determine whether or not to perform aggregation or simply forward the packet. One of the following may happen: a) If the delay constraint provided by the application can be met with probability γ , the node waits (i.e., the packet is deferred) for a certain time interval τ for other packets to arrive and aggregate the data received, forming one single packet. When the time interval expires, it forwards the data to the next sensor node where the same procedure is followed until the data reaches the sink. With probability $(1-\gamma)$, the node simply forwards the data. b) The node checks (determines) whether the delay constraint can be met only if the packet is not deferred, and forwards it to the next hop. c) The node determines whether the delay constraint cannot be satisfied in any case and discards the packet. Both the probability γ and the deferred time interval τ can be defined by the application or the user. The proposed scheme has been shown to offer significant energy savings, mainly because of the traffic reduction that is achieved by the data aggregation. In Figure 6, an example of this approach is illustrated in which three packets are combined in one packet during the deferred period τ .

Another probabilistic application-independent data aggregation scheme has been presented by He et al. (2004), in which the authors proposed an adaptive mechanism that reduces the energy consumed by sending a smaller amount of data at the MAC layer. The aggregation function is performed at a completely different layer employed between the data-link control layer and the network layer. Packets to be transmitted are passed from the network layer to the data aggregation layer, where they are concatenated in one aggregated packet, and afterwards the packet is passed to the MAC layer for transmission. The number of packets to be concatenated is determined by a control unit that makes decisions according to the current network conditions. When the aggregated packet reaches the next node, the reverse procedure is followed: the packet is de-aggregated and passed to the network layer where only packets that are destined for that node are maintained, and the others are sent for rerouting.

As previously mentioned, the decision of how many packets should be concatenated into a single one is made by a control unit based on various network and traffic conditions. Thus, when the delay at the MAC layer is high, the number of packets to be concatenated is large. On the other hand, when there is light traffic in the network, packets may not wait for others to form a concatenated packet but will be transmitted as soon as they are received. There should be an upper bound on how much time the packets are going to stay in the aggregation layer and wait for others to form a single packet, because usually there is an associated delay threshold for the delivery of the data to the final destination.

Figure 6: Data aggregation in the Q-DAP approach

Data Gathering Based on the Nature of Data

The data gathering approaches in sensor networks can be described and classified based on the nature of the data to be transmitted. Distributed data compression schemes are widely used for sending out the data collected at each gathering round. The nature of data in this case is encoded. Other techniques are based on the dissemination of metadata before sending their actual data.

Distributed Data Compression Techniques

One of the basic principles behind the minimization of the energy consumption in a wireless sensor network is to reduce the number of bits transmitted at each data gathering round. Another approach for achieving efficient data gathering is based on the source coding principle. There exist several distributed data compression techniques in the literature that compress the data generated at each node while exploiting the spatial correlations among them. However, any approach used for data coding and compression has to take into account the associated overhead cost for processing (i.e., coding and decoding). The processing cost should not be very high; otherwise, the energy savings from the information communication reduction would not improve the overall energy cost.

In general, in data compression approaches, a sensor node uses an aggregation function to encode the data available at a node before forwarding it to the sink. These schemes can be classified into multi-input and single-input coding strategies. In the first case, aggregation is performed at a node only if all input information from multiple nodes is available to explore the correlation properties among several nodes, whereas in the latter case the encoding of a node's information depends only on the information of another node (Rickenbach and Wattenhofer 2004). Moreover, the single-input coding strategies are further divided into the self-coding and foreign-coding techniques. In the self-coding strategies, data are only allowed to be encoded at the producing node and only in the presence of side information from at least one

other node. In the foreign-coding techniques, a node is only available to encode raw data originating at another node as it is routed toward the sink using its own data. In their work, the authors introduced two algorithms to solve the minimum-energy gathering problem, which is the minimization of the total energy consumption in the network for every round of data gathering. Specifically, in the case of foreign coding the minimum-energy gathering algorithm (MEGA) was proposed, which first computes a shortest path tree rooted at the sink using Dijkstra's algorithm. Consecutively, the algorithm computes for each sensor node u_i a corresponding node u_j that encodes the packet p_i using its own data, and this procedure results in a coding tree. For the computation of a coding tree, an algorithm solving the directed minimum spanning tree problem is used. Once a packet is encoded, it is routed at the sink following the shortest path, because recoding and further coding are not possible. MEGA yields a minimum-energy data gathering topology of $O(n^3)$, where n is the number of sensors in the network. Furthermore, the authors also proposed an approximation algorithm, namely the low-energy gathering algorithm (LEGA), for the case of self-coding in order to solve the problem of finding a minimum-energy data gathering tree, which is known to be NP-complete.

Another approach that makes use of the side information presence in one node is described by Chou, Petrovic, and Ramchandran (2003), where the removal of the inherent correlation in the sensors is achieved through a distributed compression algorithm. Simple lightweight encoders exist in every sensor node, and a more complex decoder exists at the gathering node (i.e., the sink). The nodes do not need to know the correlation structure in order to encode their data; they only need to have knowledge of the total number of bits that will be used for encoding. This kind of information is provided by the sink, which has global knowledge of the correlations that exist among the sensors of the network. This approach can be combined with other energy-saving techniques, such as aggregation of data, resulting in a more energy-efficient strategy for

data gathering. Furthermore, Tang, Raghavendra, and Prasanna (2003), proposed an energy-efficient distributed coding scheme called energy-efficient distributed source coding (EEADSC) that exploits the spatial correlation in data collected from nodes forming a cluster, based on the use of a Lagrangian cost function. This approach aims to compensate for the high energy cost incurred by the coding and decoding processing, by not allowing the decoder to directly communicate with the encoder. The EEADSC coding scheme uses trellis-coded quantization (TCQ), which results in the reduction of the bits transmitted and can be also combined with other data aggregation techniques to achieve greater energy savings.

Dissemination of Metadata

Sensor protocols for information via negotiation (SPIN) protocols belong to a family of adaptive negotiation-based information dissemination methodologies suitable for wireless sensor networks, suggested by Heinzelman, Kulik, and Balakrishnan (1999). According to this paradigm, sensors use metadata to describe their sensing data, whose size is small compared to data's size. Every time a sensor has data to send, it advertises it to its neighbors by sending an Advertisement (ADV) message packet containing only the metadata. Then, the nodes that have received the ADV packet and are interested in the data advertised send back a request for data (REQ) message. Finally, the node sends its actual sensed data. In an enhanced energy-aware implementation of the protocol, a low-energy threshold is defined for each sensor. When a sensor node observes that its energy is approaching this threshold, it reduces its participation in the whole procedure of the protocol, meaning that it will not initiate the three stage handshake if it does not have sufficient energy to complete all of the three stages. In this way, data are gathered to the base station in each round and result in an energy-aware gathering paradigm.

Inquiry-Based Data Gathering

In wireless sensor networks, usually the sensor nodes collect information about their environment (e.g., measuring the temperature for a given region) and send their readings to the sink either continuously, periodically, or whenever an event occurs that triggers such data dissemination (e.g., a value threshold has been exceeded). The majority of the protocols previously described have assumed this type of data collection process. However, in some cases on-demand data gathering may be required. This happens when a user outside the sensor network desires to collect data for a specific task by sending a declarative query to the sink. The sink proceeds in transmitting the query to all the nodes that are responsible for providing an answer to the query. The nodes send their readings back to the sink through a multihop route, and the intermediate nodes might perform some sort of aggregation to the data.

The Cougar approach (Yao and Gehrke 2002), treats the sensor network as a huge distributed database system in which each sensor node holds part of the data. In the proposed architecture, there is a query proxy layer on each node that interacts with both the routing and the

application layer. There also exists a query optimizer that, after receiving queries from the outside world, generates a query processing plan that results in an efficient way of computing the query. It also elects a leader node in which the in-network aggregation will take place, or, alternatively, partial aggregation can be executed at the intermediate nodes to reduce the data size. One drawback of this approach is that the in-network computation requires synchronization among sensor nodes along the communication path, because nodes have to wait for their neighbors' results for the aggregation.

A similar approach is presented by Madd et al. (2002), in which a generic aggregation service, namely, the tiny aggregation (TAG), is developed for ad hoc networks. Within the context of this scheme, a user from outside the network poses queries to the sink that are forwarded to all nodes. Sensors that respond to the query send their data back to the sink following a routing tree rooted at the sink. As data flow to the sink, they are aggregated to the intermediate nodes according to a defined aggregation function. The TAG approach consists of two phases: a distribution phase in which aggregate queries are pushed into the network, and a collection phase in which the aggregate values are routed up from children to parents until they reach the root. As in the Cougar approach, synchronization is required in order for parents to wait for their children's readings to perform the aggregation function and reduce data size.

Based on the previous two approaches that implement data gathering by posing queries to the network, a variety of other methods have been proposed that use similar Techniques and, in some cases, suggest enhancements. temporal coherency-aware in-network aggregation (TiNA; Sharaf et al. 2004), for example, provides a further improvement in terms of energy savings with some reduction in the quality of the data. A routing tree rooted at the sink is used for the propagation of the query and the collection of the results. Another unique feature of this approach is that it introduces a tolerance clause (tct) into the query, which represents the maximum change that can occur in the overall quality of data (and is defined by the user). For example, a tct of 5 percent signifies that values with changes lower than 5 percent will not be reported and calculated for the final result of the query. Consequently, energy reduction is achieved because fewer data are transmitted with the loss of the corresponding quality of data. Depending on the desired accuracy of the results, different levels of energy reduction can be provided.

Finally, the adaptive periodic threshold-sensitive energy-efficient sensor network (APTEEN) protocol (Manjeshwar, Zeng, and Agrawal 2002), also makes use of queries posed by users to gather the data generated in the network. This scheme categorizes the queries into three types, depending on the type of data—historical, on-time, and persistent queries—all of which are answered by the sink. The clustering algorithm used in Heinzelman (2000) is used to partition the network into clusters, and cluster heads are charged with the aggregation of data. Furthermore, adjacent nodes that sense similar data form pairs. The APTEEN protocol achieves lower energy consumption by allowing only one sensor of every pair to send data at each round, letting the other go into sleep mode.

Selecting Subsets of Sensors for Data Gathering

Data gathering in sensor networks has been proven to be a costly operation, because sensors consume a great amount of energy when receiving and transmitting data. All the approaches presented above used different methodologies and aggregation functions to reduce data size. However, another important category of data gathering protocols exploits the data correlation provided from sensor readings that are placed close to each other, but from a different perspective. At each round, not all sensors need to send their data to the sink, and thus only a subset of nodes should be selected to transmit.

Following this paradigm, Gupta et al. (2005) investigated the problem of selecting a connected correlation-dominating set that can be used for data gathering. The connected correlation-dominating set forms a connected graph, and its signal values are sufficient to derive the signal values of all the sensors of the network with sufficient accuracy. The approach first finds the correlation existing among the sensors and afterward enforces an algorithm for finding the connected correlated subset of nodes. Similar to this approach, Choi and Das (2005) proposed the use of data reporters for transmitting data to the sink at each round. The idea is to allow only a set of k sensors, named data reporters, to send data to the sink while the remaining cache their readings and send them during the following rounds, thus saving energy. Every node takes turns being selected as a data reporter. The number k of data reporters is selected to be sufficient for a desired sensing coverage defined by the users or the applications. The coverage is inversely proportional to the energy savings; the lower the desired coverage, the longer the data reporting latency in each sensor. For the selection of the k data reporters in each round, three schemes were developed: the non-fixed randomized selection (NRS) as well as the non-fixed and fixed disjoint randomized selection (N-DRS and F-DRS, respectively). In the first case, the selected k sensors in one round may not be different in the next round, whereas in the latter case, the set of k data reporters in a given round is completely different from the set selected in the next rounds.

Chen, Guan, and Pooch (2004) attempted to minimize the energy dissipated by reducing the dissemination of redundant data. The proposed approach provides services for data retrieval at different levels of details, depending on the application. Nodes that cover the same sensing area collect correlated data; therefore, not all nodes need to transmit their readings. Again, during each gathering round, a subset of nodes is selected whose readings provide the desired resolution data level. Less detail is acceptable depending on the user's specifications. Therefore, different levels of energy savings are achieved.

A completely different approach for data gathering is explored by Qi, Xu, and Wang (2003). The authors do not exploit the correlation of data as in the above approaches; instead they propose a mobile-agent-based collaborative signal and information processing scheme. Nodes do not send their raw data to the sink, but mobile agents are deployed that can migrate from node to node, gather the data, perform processing, and return to the sink. Although this

approach improves energy consumption, it requires additional overhead costs for the generation and migration of the mobile agents.

Data Gathering in Mobile Environments

All of the approaches for data gathering in wireless sensor networks presented earlier in this chapter have considered cases in which the sensor nodes are mainly static and have little or no ability to move. Indeed, this is the most common scenarios in sensor networks, where sensors are deployed in an area and are usually immobile, thereby forming a wireless fixed network. However, protocols have been proposed in the literature for efficient data gathering on mobile sensor networks, where the sensors can move either by outside force or by their corresponding mobility component. For example, a sensor may be attached to a moving device especially designed for tracking purposes. In these cases, because of the mobility of the sensor nodes, the network topology changes quickly and continuously; therefore, many of the aforementioned protocols may not be effective or adequate for data gathering and monitoring under these circumstances.

Liu and Lee (2004) proposed a cluster-based protocol for power-efficient data gathering in mobile sensor networks based on the LEACH protocol introduced by Heinzelman, Chandrakasan, and Balakrishnan (2000). Similarly to the original LEACH protocol, the network is partitioned into clusters and a different sensor may act as cluster head in each gathering round for sending all the gathered data of its members to the sink. The cluster formation, however, is different from the case where the nodes are static, because the sensors move around within a prespecified region. At each round, the sensors may decide to become members of a different cluster and move away from their previous cluster head. In this case, the cluster formation procedure may be called more often, resulting in increased energy consumption.

The formation can be performed by first electing the cluster heads and having these nodes broadcast advertisement messages to all the nodes, including their position, speed, and direction. Sensors in turn calculate the distance between themselves and all cluster heads and, taking into consideration their relative direction, decide which cluster to join. After the formation of the clusters has been completed, the cluster heads collect the data from their members, perform some sort of aggregation, and send the data to the final destination (i.e., the sink). Because of the high power consumption and to reduce the probability that the energy of a few sensors get depleted quickly and unfairly, various algorithms for cluster head selection that will minimize the total amount of energy consumed at each round have been proposed in the literature. Experiments have demonstrated that this approach provides a power-efficient data gathering strategy for mobile sensor networks.

Another approach, which also constructs clusters for data aggregation in sensor networks that have two kinds of nodes that can be either mobile or stationary—relay and sensor nodes—has been described in the work of Chae et al., (2004). The members of a cluster perform their tasks (e.g., sensing, data dissemination, etc.) at specific intervals

and during their idle time can be put into sleep mode to save energy. Each relay node broadcasts a message Relay node ID (RID) with lifetime to all of the sensor nodes in a cluster. If there are no sensors that operate for the real-time monitoring, the relay node and the cluster members are put into power-saving mode. Slightly before the lifetime expires, they wake up and perform their tasks until another RID with larger lifetime broadcast occurs.

RELATIVE PERFORMANCE COMPARISON

In the following section, we present a relative qualitative comparison of the different data gathering approaches and highlight their respective merits, drawbacks, and performance. Specifically, we summarize the functionality and outline the basic operational characteristics of each category, and then we present a table that provides a comprehensive comparison of the various approaches against different performance metrics of interest that have been described in this chapter. The various data gathering and monitoring approaches that have been presented take into account different design objectives and principles, and therefore aim to optimize different performance parameters and metrics (e.g., energy consumption, delay/latency, accuracy/loss of data, etc.).

More specifically, with respect to the hierarchical and nonhierarchical strategies, the protocols that belong to the first category present in principle better energy efficiency. As a result, in all the methods that belong to the hierarchical approaches (i.e., cluster-based, chain-based, and tree-constructive protocols), the network lifetime is increased at the cost of the delay. Furthermore, associated with the hierarchical approaches is an initialization phase that is required for the definition of the different layers of hierarchy, as well as maintenance costs required for the management and reconstruction of the hierarchical approach during the data gathering operation. It has been also demonstrated that the energy cost introduced by data aggregation is negligible compared to the corresponding communication and data transmission cost. Depending on the data aggregation function used at each sensor node (e.g., average, sum, discard of duplicate packets), the final data delivered to the collection center may be different from the original data, resulting in some level of loss in the data accuracy.

On the other hand, the nonhierarchical approaches (e.g., flooding, gossiping, etc.) do not need to go through any initialization phase and in general present lower implementation complexity and maintenance costs. All of the sensor nodes that are involved in the data gathering operation send their data to all of their neighbors without performing any in-network processing (e.g., data aggregation). As a result, all of the sensors consume larger amount of energy and the corresponding network lifetime is decreased. With regard to consideration of the delay constraints, the nonhierarchical protocols deliver data in a more timely manner during their first periods of operation or when they operate under low traffic load. However, as the traffic load increases and the data packets that travel through the network increase, severe delays are observed

from collisions and bottlenecks; this also has a significant negative impact on the achievable network throughput.

With respect to the probabilistic and routing independent approaches, in addition to their distributed nature and demonstrated energy efficiency, one of their key principles is that they can be combined with any other energy-aware routing protocol to attain even higher energy gains. Furthermore, because of their distributed, probabilistic behavior, they can decide independently whether or not to perform in-network processing to reduce the amount of data transmitted, thus succeeding in satisfying the delay constraints posed by the application.

The data gathering approaches that are based on the nature of data mainly aim to accomplish the data gathering operation in an energy-efficient manner. More specifically, the protocols that perform data compression in the presence of correlated data transmit fewer amounts of data with the trade-off of the occurrence of some information loss (provided that the compression is not lossless), while the use of encoders and decoders increases the processing cost and latency. If metadata is transmitted, there is no additional processing cost and the total amount of data packets traversing the network is reduced. With reference to the inquiry-based data gathering protocols, the collection center poses different queries to the network that are addressed only by a subset of nodes, thus reducing the total amount of information collected at the center. The accuracy of the collected data depends on whether or not the nodes perform some kind of aggregation as well as the type of the aggregation function utilized. Moreover, in certain protocols, sensor nodes do not transmit their reading if there is a small variation from the previous transmission, thus resulting in greater information loss in some cases.

Finally, the last class of protocols considered here does not perform in-network processing but explores the correlation of the sensor readings by not allowing some sensors to transmit in specified communication rounds. The main characteristic of these approaches is that the energy consumption can be controlled (i.e., reduced) by adjusting the subset of sensors to transmit at each cycle, at the cost of reducing the corresponding achievable network sensing coverage. Table 1 presents a qualitative relative comparison of the aforementioned methods against a common set of parameters.

CONCLUSION

Remote sensing is expected to become an integral part of our lives as we strive to use sensor technologies to monitor our surrounding space for a variety of applications such as security, health, education, comfort, environment, traffic, safety, and so forth. These applications require tight coupling with the physical world, as opposed to the personal communication focus of conventional wireless networks; therefore, the wireless sensor networks pose significantly different design, implementation, and deployment challenges. Sensors should be networked to facilitate the transmission and dissemination of the measured/monitored parameters to some collector sites where the information is further processed for decision-making purposes. Multiple sensors offer fault tolerance and better monitoring capabilities of parameters that present both

spatial and temporal variances, and can provide valuable inferences about the physical world to the end user.

In this chapter, we focused on the problem of energy-efficient data monitoring and gathering in sensor networks. The sensor networks should dynamically adapt to the system and topology changes, and at the same time they need to balance the trade-offs among various performance metrics. Therefore, we first identified the major performance metrics of interest for the data monitoring and gathering process, and we discussed the related traffic and data correlation models. We then identified and reviewed various issues associated with the sensor node deployment patterns, which are closely related to the effective data monitoring. Furthermore, we described several data gathering approaches by classifying them into diverse categories according to the different features and design dimensions of the wireless sensor networks, and we presented some indicative associated protocols. Finally, we provided a relative comparison of all of the different approaches—outlining their major merits and drawbacks, highlighting their differences, and evaluating their relative behavior based on a common set of parameters.

GLOSSARY

Chain-Based Protocol: A network protocol that constructs chains of nodes for the performance of a specific task.

Cluster: A group of similar objects that are grouped together to perform a specific task.

Cluster-Based Protocol: A network protocol that constructs clusters of nodes for the performance of a specific task.

Data Aggregation: Any process in which information is gathered and redefined into a summary form based on some rules or criteria.

Data Compression: The process of reducing data size without significant loss of information, usually by encoding information using fewer bits than the ones used by an unencoded representation.

Data Correlation: A measure of the degree of dependency between two or more variables that represent data.

Data Fusion: The process of combining data from different sources to eliminate redundant transmissions and provide a rich, multidimensional view of the environment being monitored.

Data Gathering: The process of collecting the data of multiple sources to, usually, a single collection center.

Data Monitoring: The process of periodic or continuous measurement of the data transmitted and received in a network.

Hierarchical Protocol: A network protocol that assigns/recognizes different roles and functionalities within the components of a network. Components are classified according to various criteria into successive levels or layers.

Non-Hierarchical Protocol: A network protocol in which every component can perform similar roles and functionalities.

Self-Organization: A process in which the internal organization of a system is formed and maintained automatically without being guided or managed by an outside source.

Tree-Constructive Protocol: A network protocol that constructs trees that span the network, in which the

nodes can either be leaves or internal nodes, for the performance of a specific task.

INTRODUCTION

Advances in microelectronics have enabled the development of exceptionally tiny sensor nodes that have the ability of measuring ambient conditions such as temperature, pressure, humidity, light intensity, and motion (Akyildiz et al. 2002). The sensed data can then be transmitted through an on-board radio transmitter to single or multiple *base stations* (BSs) where it can be further processed. The tiny size and inexpensive cost of such emerging sensor nodes has encouraged practitioners to explore using them collaboratively in a network formed in ad hoc manner. Such a networked sensor system not only is cost-effective but also can provide fast and accurate information gathering in remote and risky areas. Figure 1 depicts a typical sensor network architecture. The BS acts as a gateway for linking the sensors to multiple command nodes.

The past few years have witnessed increased interest in the potential use of *wireless sensor networks* (WSNs) in applications such as disaster management, combat field reconnaissance, border protection, and security surveillance (Mainwaring et al. 2002; Burrell, Brooke, and Beckwith 2004; Agora et al. 2004, 2005).

It is envisioned that WSNs will be part of the future Internet where real-time information will be queried through sensors deployed almost everywhere in our living environments. This direction suggests that gathering and processing large volumes of data from WSNs will continue to be one of the most important problems for researchers in coming years.

However, because sensors have severe resource constraints in terms of power, processing capability, memory, and storage, it is challenging to provide efficient solutions

to the data-gathering problem. Energy limitations have been an especially pressing issue that affects the design of WSNs at all layers of the protocol stack (Akyildiz et al. 2002; Akkaya and Younis 2005). Many researchers have investigated various mechanisms such as shutting down the radio, eliminating control packets, and using topology-management algorithms (Xu and Heideman 2001; Cerpa and Estrin 2002) to reduce energy consumption in WSNs.

Data aggregation is also among those mechanisms utilized to save energy and achieve energy efficiency. It is the process of combining multiple data packets into one by looking at their contents. For instance, WSNs may have a lot of redundant data because multiple sensors can sense similar information when they are close to each other. Therefore, there is no need to send the same information to the BS more than once when a summary of the readings from those sensors can be sent. Thus, data aggregation will decrease the number of transmissions in the network, eventually reducing the bandwidth usage and eliminating unnecessary energy consumption in both transmissions and receptions.

Although data aggregation may help reduce the number of transmissions and hence energy consumption (Krishnamachari, Estrin, and Wicker 2002; Heidemann et al. 2001), it may adversely affect other performance metrics such as delay, accuracy, and security. For instance, data aggregation may cause the nodes to wait for their children to send their data in a tree topology, increasing the delay that the packets face (Erramilli, Malta, and Bestavros 2004; Akkaya, Younis, and Youssef 2005; Yu, Krishnamachari, and Prasanna 2004). In addition, it can decrease the accuracy of the result received at the

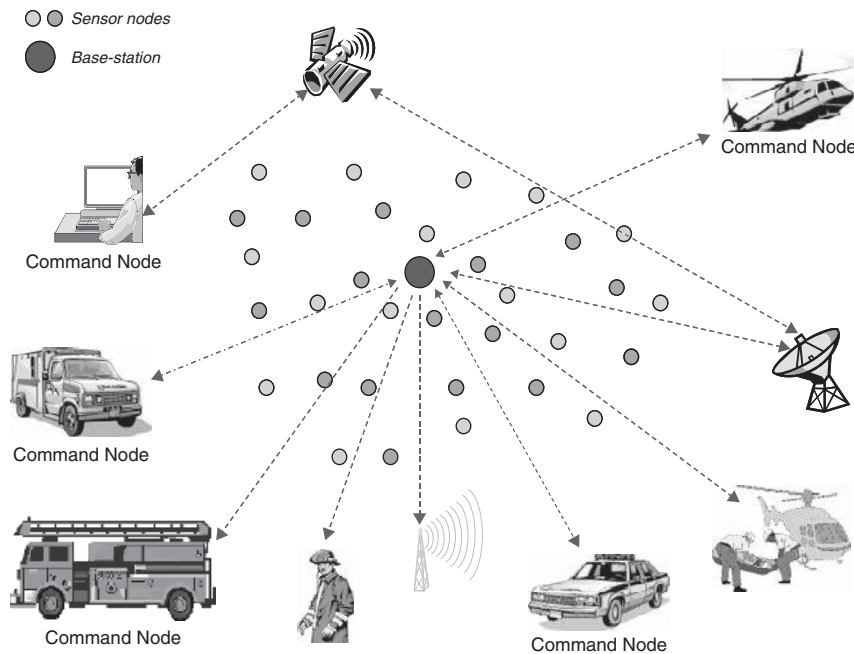

Figure 1: A typical sensor network architecture

BS because many readings from different sources are eliminated through data aggregation when the packets are en route (Solis and Obraczka 2004). Finally, security is another concern because authentication and encryption are required before packets can be safely combined (Hu and Evans 2003; Castelluccia, Mykletun, and Tsudik 2005; Girao, Westho, and Schneider 2004).

In this chapter, we will describe how data-aggregation issues are tackled in WSNs for optimal performance in terms of energy and bandwidth. In addition, we will discuss several trade-offs arising as a consequence of data aggregation in terms of latency, accuracy, and security and summarize solutions in the literature that address these issues.

The chapter is organized as follows. In the balance of this section, we will describe and motivate data aggregation and differentiate it from other in-network data-processing techniques. The second section discusses modeling of the in-network data-aggregation problem. The third section covers the impact of data aggregation on data latency. Aggregation and accuracy trade-offs are discussed in the fourth section. In the fifth section, secure data aggregation is explained in detail. Finally, the chapter's conclusion points out problems that may be subject to future research.

Motivation and Description of Data Aggregation

Given that sensor nodes are severely constrained in terms of battery lifetime, the aim is to always come up with techniques to increase such lifetime. Battery power is needed by a sensor node to perform computations with its CPU and, most importantly, to transmit and receive packets through its radio. Thus, an obvious solution would be to reduce the CPU usage and the number of transmission

and receptions. Today, we know that energy consumed for communication (i.e., transmission and reception) is much higher than computation. For instance, with the energy consumed to transmit 1 Kb of data a distance of 100 meters, it is possible to execute 3 million instructions (Sohrabi et al. 2000). Therefore, it is wise to focus on reducing the communication costs and promote more computation than communication. Note that such a reduction in the number of transmissions and receptions will also increase the available bandwidth, which is also a scarce source for WSNs.

There are many opportunities in WSNs to reduce the number of transmission and receptions because WSNs are characterized by huge numbers of nodes with considerable redundant data because of the similarity of reports sensed by sensor nodes at nearby locations as seen in Figure 2. In this example, node C does not need to transmit the same data it received from A and B on overlapping

Figure 2: Two sensors (A and B) cover an overlapping geographic region, and C may get copies of data from these sensors

Figure 3: (a) No data aggregation and three transmissions to the BS; (b) data aggregation with one transmission to the BS

region r . Instead, it can send just one copy of that data and hence save one transmission and reception.

Other cases in which the number of communications can be reduced are *aggregate queries*. These are queries where the result is computed based on the data received from every node. For example, if a query is asking for the average temperature in a region, then each sensor's value should be received at the BS and averaged. However, there is no need for the BS to receive all of the values. Instead, the average can be calculated within the network while the packets are traveling through the BS. A node can get the values from its neighbors, compute the average (i.e., create one packet out of n), and send the average to the upper nodes. This definitely reduces the number of transmissions significantly as seen in Figure 3.

Because data aggregation in WSNs is done by the intermediate nodes en route to the BS incrementally, it is usually referred as *in-network* data aggregation. Typically, an aggregation tree rooted at the BS is created with the source sensors as leaf nodes. When data are flowing toward a single BS, this aggregation tree is called *convergecast tree*, which is the inverse of a broadcast tree. A typical convergecast tree is depicted in Figure 4. In such a tree, an intermediate node can combine multiple packets, suppress them, and help calculate part of some aggregation function such as average, count, maximum, or minimum. Each intermediate node in a convergecast tree may have multiple child nodes to receive data and a parent node to transmit data.

There are several applications in which data aggregation can be employed. As mentioned, in sensor databases, data aggregation is a crucial technique for performing aggregate queries. For instance, if the sensors

are employed in an inventory-control application, the number of objects can be summed and transmitted along with the region's information to the BS. The goal is to perform the computation near the sources and then send an aggregated report (Lin and Huang 2005). Similarly, data aggregation can be used to monitor the average available energy in different parts of a region where an event is taking place (Zhao, Govindan, and Estrin 2002). Finally, it can be embedded in any WSN protocol to eliminate redundant data.

Although it is possible to reduce data transmissions and save energy through data aggregation, we note that it is not by itself adequate to extend the lifetime of the WSNs. For instance, data aggregation cannot be applied to control packets for routing or for time synchronization. Therefore, for applications that send a lot of control packets, data aggregation may not provide the desired energy savings. In addition, data aggregation may require sensor nodes to be active most of the time, which is by itself an energy-consuming task. Keeping the radio on most of the time can eliminate some of the energy gain through data aggregation, depending on the application and the network architecture.

Other Types of In-Network Processing

In addition to the data aggregation considered in this chapter, there are many other forms of in-network processing that can help reduce the size of data to be transmitted and hence help save energy. These in-network processing techniques include data fusion, data compression, data filtering, and data elimination. In this section, we will briefly describe these techniques so that the scope of data aggregation we consider in this chapter can be better distinguished from them.

Data Fusion

In-network data aggregation is often confused with data fusion. Most people assume that they mean the same thing. In fact, they are interrelated and often used interchangeably in WSN research. However, there is a slight distinction between these two techniques. Data fusion is a broader technique that includes data aggregation as a subprocess and focuses on information rather than data with the use of several interdisciplinary techniques such as signal processing, statistical analysis, machine learning, and probability. Whereas data aggregation is introduced with the need to reduce data redundancy and the number of transmissions in WSNs, data fusion

Figure 4: A sensor network and its corresponding data-aggregation tree

has already been used in the past extensively for different systems, including wired multisensor systems (Hall and Llinas 2001; Musick and Malhotra 1994). Data fusion takes multiple sources and forms of data and uses all of these data in a way such that a better picture of the observed phenomena is formed. In this way, the phenomena can be better predicted and understood and in turn controlled. Note that, as a consequence of the data fusion, the resulting information is often abstract, generalized, or summarized, and hence the amount of data is reduced. The popular and widely accepted process model for data fusion identifies five levels in a data fusion process (Hall and Llinas 2001): Level 0 is the subobject assessment, level 1 is the object assessment, level 2 is the situation assessment, level 3 is the impact assessment, and level 4 is the process refinement. In this hierarchy, data aggregation is employed in level 0, where some signal processing is performed.

Data Compression

Compression is one of the most effective methods to reduce data size. However, there is a trade-off between the compression and the size of the data to be transmitted. The larger the data, the more energy will be consumed in performing the compression. Thus, the main issue is to identify the ratio of the energy that needs to be utilized for both compression and transmission. Obviously, the advantage of compression is the possibility of data generation close to the original. Recent research has focused on proposing energy-efficient encoding and decoding functions for historical sensor data (Lin et al. 2005; Scaglione 2003). Most research has concentrated on JPEG formats for images and MPEG formats for video.* The motion-compensated encoding may be employed to reduce the bit rate (Obraczka, Manduchi, and Garcia-Luna-Aceves 2002). The discrete cosine transform, which is widely used in JPEG and MPEG, is computationally intensive; it is doubtful that energy-limited sensors can handle it. The alternate approach is to use the discrete wavelet transform, which can be used in both the JPEG-2000 and MPEG-4 standards.

Data Elimination

The easiest way to eliminate some of the packets is to perform temporal aggregation or decrease the data-sampling rate of the sensor nodes. In temporal aggregation, a node caches the reading and compares it with the next reading. If there is not a significant difference between the readings, it might not make sense to send it again. A threshold for the difference of consecutive readings can be defined in order to make the sending decision as done in Cougar (Yao and Gehrke 2002) and TEEN (Manjeshwar and Agrawal 2001). In this way, the number of transmissions from a sensor can be significantly reduced. Similarly, depending on the application level interest, the period for collecting a reading from a sensor node can be increased. This especially makes a significant difference if the sent data are image or video data.

Data Filtering

Data filtering refers to the elimination of incorrect, invalid, or unknown noisy sensor data. It is a part of data fusion in WSNs and has been extensively used to eliminate redundancy and noise, clean the data, and make predictions based on spatio-temporal characteristics (Faradjian, Gehrke, and Bonnet 2002; Cheng and Prabhakar 2003; Elnahrawy 2003; Wen, Agogine, and Kai 2004). The goal in most of these approaches is to model the sensor data by using statistical techniques such as Bayesian-based approximation and Gaussian distribution to handle the imprecision. Handling imprecision and modeling sensor data enables future estimations, eliminates outliers, and hence reduces the number of transmissions.

In this chapter, we will mainly focus on spatial data aggregation and its networking aspects in WSNs. The other forms of in-network processing mentioned above are beyond the scope of this chapter.

MODELING IN-NETWORK DATA AGGREGATION IN WSNs

Given that in-network data aggregation reduces energy consumption, the main research problem is how to create a convergecast tree to maximize the lifetime of the WSN. Specifically, the main problems to consider are how to create the convergecast tree, how to select the routes, and where to do the aggregation in this tree. In this section, we will describe the protocols that modeled the data-aggregation problem using different approaches.

Tree-Based In-Network Data Aggregation

Finding the optimal convergecast tree in a WSN can be modeled as a *minimum Steiner tree* (MST) problem, which is known to be NP-hard (Krishnamachari, Estrin, and Wicker 2002). MST is, in fact, a multicast tree with minimum number of edges. Because a convergecast tree is the reverse of a multicast tree, it can be used in modeling a convergecast tree. Then an MST can be defined as follows: Given a complete graph $G = (V, E)$ and a subset $S < V$ of required vertices, a Steiner tree is a subtree of G that includes all of the vertices in S . Assuming that each source node transmits only once in a convergecast tree, an MST should have the minimum number of edges. For example, Figure 5 shows three convergecast trees with different numbers of edges. However, the third one (i.e., MST) is better in terms of energy savings because it provides the minimum number of transmissions to the BS.

Because the optimum solution to the MST problem is NP-hard, several suboptimal schemes have been proposed. We now describe three different heuristics for this problem: center at the nearest source, shortest path trees, and greedy incremental trees.

Center at the Nearest Source

In the *center at the nearest source* (CNS) heuristic, the idea is to determine the node that is closest to the BS and have all of the other sensor sources send their data to this particular node. This node receives all of the data, aggregates them, and sends the aggregation to the BS. Therefore, it

* The acronyms are derived from Joint Photographic Experts Group and Moving Picture Experts Group, respectively.

Figure 5: Possible convergecast trees for a network with three data sources. MST gives the optimal cost in terms of number of transmissions to the BS.

is named the *center*. It is more likely that this center node would be on the path of most of the sensors and thus will help reduce the number of transmissions significantly. Note that with this method, the MST of the WSN is optimized the longest trunk (i.e., with the maximum number of nodes at the last level of the tree).

Shortest Path Trees

The *shortest path trees* (SPTs) heuristic proposes to determine the shortest path from each sensor to the BS. Data are then aggregated at each common intermediate hop of these shortest paths through the BS.

Greedy Incremental Trees

In the case of *greedy incremental trees* (GITs), the convergecast tree is built sequentially to merge paths and provide more aggregation. First, the shortest path from the closest source to the BS is found. Then the other sources start connecting to this shortest path, forming a convergecast tree. This heuristic has been shown to provide an approximation ratio of 2 (Takahashi and Matsuyama 1980).

All of these heuristics have been implemented by Krishnamachari, Estrin, and Wicker (2002), and a comparison in terms of energy gain is made by trying different number of sources, transmission ranges, and distances to the BS. The results have shown that in all cases 50 percent to 80 percent energy savings are achieved with respect to the case where no data aggregation is performed. In addition, the energy saving through SPTs and GITs are more significant because they provide aggregation at all levels of the tree. However, this type of aggregation will increase the latency of packets, which will be discussed later.

Cluster-Based, In-Network Data Aggregation

Given the resource constraints of sensor nodes, some researchers considered partitioning the network into clusters and deploying cluster-heads to perform data aggregation (Chen, Liestman, and Liu 2005; Kumar et al. 2003; Heinzelman, Chandrakasan, and Balakrishnan 2000; Lindsey and Raghavendra 2002; Çam et al. 2006). The job of these cluster-heads is specifically aggregating the data received from the sensors and transmitting them

to the BS. In most scenarios, they do not perform any sensing. In addition, these aggregator nodes can be more resource-rich than the sensors (Chen, Liestman, and Liu 2005; Kumar et al. 2003; Lee and Wong 2006). Such a resource-rich node can significantly alleviate the load of data aggregation and transmission from the sensor nodes, which eventually increases the lifetime of the WSN. Note that depending on the availability of these resource rich nodes, they can also be employed for data aggregation at any level of the convergecast tree. Thus, MST-based heuristics can also be applied to these kinds of heterogeneous WSNs where powerful nodes exist.

Low-energy adaptive clustering hierarchy (LEACH) (Heinzelman, Chandrakasan, and Balakrishnan 2000), *energy-efficient and secure pattern-based data aggregation* (ESPDA) (Çam et al. 2006) and *power-efficient gathering in sensor information systems* (PEGASIS) (Lindsey and Raghavendra 2002), however, do not consider such powerful nodes and thus elect a cluster-head among the sensor nodes that performs the data aggregation. Although LEACH considers clusters where each sensor can reach the cluster-head within one hop, PEGASIS creates chains of sensor nodes in which a leader is designated as the aggregator. ESPDA, on the other hand, considers clusters with multihop routes. In all of these approaches, sensor nodes take turns to be elected as the cluster-head so that the load of being cluster-head is distributed evenly among the sensor nodes in the network.

Application-Specific, In-Network Data Aggregation

Because data aggregation mostly focuses on eliminating redundant data, in most cases application information is useful to reduce such redundancy. This idea is initially utilized in directed diffusion (Intanagonwiwat, Govindan, and Estrin 2000) which is one of the famous and widely used routing paradigms for WSNs. Directed diffusion suggests the use of attribute-value pairs for the data, and queries are created in an on-demand basis by using those pairs. Attribute-value pairs such as name of objects, interval, duration, and geographical area are used to name the data. This naming is then exploited to perform in-network aggregation. Once the data are

known through low-level naming, intermediate nodes receiving the data can cache, filter, and suppress the data before transmitting to the parent node. With this method, each sensor can perform in-network data aggregation, and redundancy can be eliminated significantly.

An improvement to directed diffusion's application-specific, in-network data aggregation is to both utilize application information and minimize the number of edges in the convergecast tree. Specifically, this solution applies application-specific aggregation in a MST. A sample implementation of this approach is done in Heidemann et al. (2001) by performing the aggregation as close to the data sources as possible as in the case of the CNS heuristic proposed in Krishnamachari, Estrin, and Wicker (2002). Not only can the approach provide a 42 percent traffic reduction with respect to nonaggregation, but also it can handle nested queries (e.g., group by queries) perfectly with CNS heuristic.

Application-specific, in-network data aggregation is promising for future large-scale sensor databases in which a lot of complex queries are submitted frequently. One obvious disadvantage of these approaches is the need to reprogram the sensors for each different application. The used naming schemes are application-dependent, and each scheme should be defined a priori. Moreover, the matching process for data and queries might require some extra overhead at the sensors.

Structure-Free, In-Network Data Aggregation

The above described in-network aggregation approaches focus on the creation of a convergecast tree and the clusters and determination of aggregation points that need to be done upfront when the WSN is deployed for an application. This requires a lot of signaling overhead in creating, maintaining, and updating the proposed structures. Therefore, recently researchers have started to investigate the potential of using structure-free data aggregation (Enachescu et al. 2004; Fan, Liu, and Sinha 2005). For instance, in Enachescu et al. (2004), a randomized algorithm is proposed to provide a constant time approximation to the problem of determining optimal convergecast tree that is NP-complete. The authors claim that the approach will eliminate the need for special data-routing structures for some aggregation functions. Similarly, in Fan, Liu, and Sinha (2005), data aggregation is performed without using a predefined convergecast tree. The idea of spatial aggregation is based on *data-aware anycast* (DAA), which is performed at the *medium access control* (MAC) level. Rather than transmitting a data packet to a particular node, the goal is to determine the nodes that have packets ready to transmit and then send the packets to them. This increases the chance for spatial aggregation without referring to any convergecast tree. Furthermore, to get packets from multiple nodes ready at a certain node, that node delays its own transmission for a random amount of time. Simulation results have shown that the proposed approach based on DAA and randomized delay can decrease the number of transmissions by 77 percent when compared to opportunistic aggregation in which packets are aggregated whenever there is an opportunity.

THE IMPACT OF DATA AGGREGATION ON DATA LATENCY

Although data aggregation is confirmed to save significant energy in WSNs, there is a price for it: an inherent trade-off between energy and latency. Data aggregation may increase the end-to-end latency for the data packets and hence may not be applicable for the applications where end-to-end latency is critical. This is an important problem for large-scale sensor databases, where users submit frequent aggregation queries and would like to get the results within a certain amount of time. Such a typical query can be specified as "Report the average (maximum, minimum, etc.) measurement (temperature, pressure, radiation, etc.) in a certain region within D time units every T time units," where $D < T$.

The increase in the end-to-end latency results from increased wait times for the intermediate nodes when performing data aggregation. Each intermediate node may have multiple children, and the data-gathering process from these children may not always be synchronized because of the unbalanced structure of data-aggregation trees, node failures, congestion, and packet losses. Therefore, the increased latency for the aggregated packets becomes an issue when convergecast trees are in use. In this section, we first provide information about time-synchronization issues for performing data aggregation and then we summarize the aggregation approaches in WSNs for minimizing the latency while at the same time achieving the desired level of aggregation.

Time Synchronization for In-Network Data Aggregation

To eliminate redundant packets at an aggregating node, the node should make sure that these packets were generated at similar times. Therefore, the packets should be time-stamped with a precision on the same order as the event frequency when they are generated. This is more stringent than in traditional wired networks as far as the data-aggregation process is considered. An imprecise time-synchronization method will not only cause the sensor to fail to recognize the duplicate packets but also affect the waiting time of a packet in a node. In addition, to perform data aggregation, the scope of the time-synchronization algorithm should cover a wide area because the packet is traveling via multihops to the BS and being cached at some intermediate nodes.

Given the criticality of a precise and persistent time-synchronization algorithm, many new algorithms were proposed specifically for WSNs (Elson, Girod, and Estrin 2002; Sichitiu and Veerarittiphan 2003; Elson and Römer 2002). These algorithms updated the current synchronization algorithms such as network time protocol by considering the energy and communication constraints of the sensors in the design.

Modeling the Delay-Constrained Data-Aggregation Problem

When latency is the concern, the data-aggregation problem can be modeled as a constrained MST problem that

is also an NP-hard problem (Kompella, Pasquale, and Polyzos 1993). In that case, the problem should ensure two things:

1. For all paths from source sensors to the BS, the end-to-end latency should be less than the desired deadline.
2. The final convergecast tree should provide the minimum possible energy consumption.

It is a nontrivial problem to both determine a convergecast tree that will minimize the energy consumption and ensure that each path will meet the timing constraints. Therefore, there exist no heuristics to the constrained MST problem in WSNs. However, there are different approaches with different assumptions.

One approach that deals exactly with the constrained MST problem is based on utilizing some special packet-scheduling techniques such as *weighted fair queuing* (WFQ) (Erramilli, Malta, and Bestavros 2004). This approach initially forms a convergecast tree that suits contemporary best-effort traffic. It then utilizes WFQ to support on-time delivery of delay-constrained (real-time) data. The idea is to identify the longest path in terms of hop counts on the initial convergecast tree for which the end-to-end delay is acceptable. A work-around mechanism is presented to ensure timeliness of packets on unfeasible paths (i.e., paths that cannot meet the desired deadline) by modifying the tree so that the packets are aggregated at another relay node that is closer to the BS. It is proved in this work that when a feasible path is found for the longest path in terms of hop counts among the real-time sources, the other sources connecting to this longest path can meet the end-to-end delay bounds. Simulation results have shown that the approach provides significant increase in timeliness at the price of a slight increase in energy consumption when compared to non-WFQ-based aggregation. The approach maintains the same level of timeliness for low traffic rates and slightly increases deadline misses for reasonably higher rates.

Another solution that considered a slightly different version of the same problem is proposed in He et al. (2003). In this case, the aim is to reduce the end-to-end delay rather than to provide certain guarantees. The proposed protocol is an *application-independent data aggregation* (AIDA) that does not depend on the type of the application. However, this solution works between the MAC and the network layers, which is the difference from Erramilli, Malta, and Bestavros (2004). The main idea is to concatenate a number of packets at the MAC layer at once, called *degree of aggregation*, to minimize the number of transmissions and packet overhead for accessing the channel. The concatenated packets are decomposed when reached to the destination. This is an adjustable parameter, and a feedback-based mechanism is used to adjust it based on the changing traffic conditions. Queuing delay is the factor used as feedback. By eliminating the need for accessing the channel and transmission for packets, the energy is saved and end-to-end delay is not affected and even decreases in high loads. However, the approach just considers aggregation at the

MAC layer, and there is no optimization at the network layer. Therefore, the proposed approach is not suitable for implementing typical aggregation functions such as sum and average. Furthermore, one main disadvantage of their approach is that when the concatenated packet is dropped or lost for any reason, the recovery process will be extremely expensive, reducing the energy and latency gains.

The constrained MST problem may become simpler when the convergecast tree is known a priori. In this case, the problem reduces to scheduling the transmissions or adjusting the transmission time on each link so that for each path the end-to-end deadline is met. This problem is studied in Yu, Krishnamachari, and Prasanna (2004) under a nonmonotonic energy model—namely, *quadrature amplitude modulation* (QAM). Using this model, the bit rates on each link can be adjusted for a desired latency. The more power used for transmitting a bit, the faster it travels and hence the delay is reduced. Therefore, the aim is to minimize the total energy consumption on a path (and hence on the whole convergecast tree) while keeping the latency in check. A distributed online dynamic programming-based approach is proposed to minimize the energy usage (Yu, Krishnamachari, and Prasanna 2004). However, the solution assumes minimal interference among the nodes at the MAC layer, which is a difficult task to achieve in practice.

A possible and simple solution when the convergecast tree is known is to divide the given deadline into the number of nodes on a particular path and allow each node this amount of time to perform the data aggregation (Roedig, Barroso, and Sreenan 2004). In this case, each sensor node knows the maximum amount of time it can wait before aggregating the packets it has and transmitting to the parent node. However, this waiting time may greatly affect the accuracy of the data received at the BS as will be discussed later. Depending on the latency constraint, the accuracy performance will differ. For instance, if the latency is especially small, then the waiting time for a sensor will be especially short and hence the accuracy of the data at the BS will be reduced because the number of children contributing the aggregated data will be smaller. Therefore, this factor should also be included when formulating the solution.

Aggregation Delay and Network Topology

The end-to-end delay in data aggregation can also be affected by the network connectivity. The network connectivity is an issue in WSNs because most of the time the radios of sensors are shut down to save energy. Therefore, not all of the sensor nodes are always available for performing data aggregation. An interesting research problem at this point is to look at the delay performance of data aggregation under the influence of topology control. This problem is studied in Erramilli, Malta, and Bestavros (2004), where the possible effects of the network topology on the performance of data aggregation in terms of energy, delay, and fidelity is investigated. The aim is to maintain network connectivity with the minimum possible number of active sensor nodes and maximizing in-network data aggregation.

The simulation results have shown that topology management can have a detrimental effect on the network in terms of increased delays: Because connectivity strives to maintain minimum possible number of active nodes for energy considerations, the aggregation process is delayed until some of the nodes wake up. The increase in delay resulting from topology control may reduce the savings in energy from aggregation. Hence, in the presence of in-network data aggregation, careful coordination between routing and topology control is needed. In addition, shorter and fatter (i.e., dense) aggregation trees should be employed for best energy-delay trade-off results.

THE IMPACT OF DATA AGGREGATION ON DATA ACCURACY

In WSNs, it is critical to decide how long a sensor node will wait for its children to forward the aggregated data to the upper nodes in a convergecast tree in order to decide the level of accuracy of the data at the BS. Accuracy is measured by the number of nodes contributing to the result received at the BS. For example, if the average temperature is computed in a specific region, picking two sensor readings is less reliable and accurate than picking twenty readings. The more nodes contribute, the more accurate the data will be. Given that sensors are employed in sheer numbers, the accuracy of the received data at the BS can be adjusted based on the utilized aggregation and routing mechanism.

However, determining the number of sensors nodes contributing to the result is a difficult problem because such a decision can also affect energy and latency performance. Although an increased number of readings means increased accuracy of the result, collecting those readings from the sensors may increase the waiting times at the intermediate nodes. In addition, the increase in the number of contributions will mean an increased number of transmissions, which eventually increases the energy consumption of the sensor nodes. This section covers the description of approaches that explore the trade-off among accuracy and other metrics such as energy and latency when performing in-network data aggregation. We focus especially on mechanisms pursued in sensor databases by the data management research community to decide the waiting time of a parent node before data aggregation is performed.

Determination of Waiting Times

Different mechanisms have been proposed to set the waiting time duration for a particular node before aggregating the messages from its children and forwarding the aggregation to the upstream node as seen in Figure 6. The used timing model has a strong effect on the accuracy of the received data at the BS. Three widely used timing models that have been described in Solis and Obraczka (2004) are periodic simple, periodic per-hop, and periodic per-hop adjusted.

In the *periodic simple* approach, each node is assigned a predefined and fixed amount of waiting time. The *periodic per-hop* approach, on the other hand, requires each

Figure 6: The question is, how long should node 1 wait before it performs the aggregation and forwards the packet to the BS? Note that in this case the packet coming from node 4 can be delayed more than the packets coming from nodes 2 and 3.

node to wait for all of its children so that all of them send their data and aggregation can be performed. In the *periodic per-hop adjusted* approach, the time durations are assigned based on the position of the nodes in the convergecast tree. This is also called the *cascading time-out* approach in which a node's time-out happens right before its parents. Simulation results have shown that the cascading time-out approach can provide six times more energy savings with respect to the periodic simple and periodic per-hop approaches (Solis and Obraczka 2004). Furthermore it provides exactly the same accuracy with the case when there is no data aggregation, whereas periodic simple and periodic per-hop approaches significantly decrease the accuracy (by approximately 50 percent).

The third approach is similar to epoch division approach in *tiny aggregation* (TAG) (Madden et al. 2002a) which is proposed to define a *structured query language* (SQL)-like declarative query language for expressing aggregation queries over streaming sensor data. This query language is applied as an abstraction between the user and the network protocol. Because TAG deals with aggregation queries, it does not provide any technique for eliminating redundancy. Rather, partial results for the aggregate queries are computed at the intermediate nodes, which reduces the number of transmissions.

TAG has two phases for data collection: *distribution* and *collection*. It introduces an epoch clause that represents the time to wait for getting the next answer for the query. The synchronization of the nodes in the tree to receive and transmit data is maintained through the subdivision of the epoch value into shorter intervals called *slots*. At each slot there is one level of nodes (in the convergecast tree) that are transmitting and another level of nodes that are receiving. This continues similarly up to the level of the BS as can be observed in Figure 7. Note that this is similar to the cascading time-out approach defined in Solis and Obraczka (2004).

In TAG, when the child does not have data that conform to the defined predicate, it does not send the data but rather notifies the parent node that it will not be sending data so that the parent will not wait for that node for performing aggregation. The idea in TAG is to do aggregation whenever possible in the tree through the BS.

Figure 7: Epoch-based aggregation in TAG (Wen et al. 2004)

TAG separates data aggregation and routing functions, emphasizing that data aggregation should consider what data will be collected rather than how they are collected. Note that this is a different interpretation when compared to Solis and Obraczka (2004). The main idea here is to allow the expression of aggregation logic in a separate layer than the routing layer so that the system can dynamically adjust the routing decisions based on the used aggregation function. This also gives the user the opportunity to modify the system's behavior on the fly.

The periodic per-hop approach (i.e., waiting for all the children) defined in Solis and Obraczka (2004) is also employed in Cougar (Yao and Gehrke 2002). Cougar is similar to TAG: Declarative queries are used to abstract query processing from the network layer functions such as selection of relevant sensors and to utilize in-network data aggregation to save energy. The abstraction is ensured through a new query layer that is between the network and application layers. Cougar proposes an architecture for the sensor database system in which sensor nodes select a leader node to perform the aggregation and transmit the data to the BS. The BS is responsible for generating a query plan that specifies the necessary information about the data flow and in-network computation for the incoming query and sending it to the relevant nodes. The architecture provides in-network computation ability for all of the sensor nodes as seen in Figure 8, which is redrawn from Yao and Gehrke (2002).

Although waiting for all of the child nodes can increase the accuracy of the result at the BS, it will definitely worsen the delay because not all of the child nodes send their data at the same time to the parent node. One solution to eliminate this problem is to have a perfectly balanced convergecast tree so that two nodes at the same level will face the same delay because they will have the same number of nodes under their subtrees. However, it is clear that creating a perfectly balanced tree is not always possible because of large number of sensors, random deployments of sensors, and complex tree creation operations. Thus, a mechanism that is independent from the structure of the tree and assigns waiting times

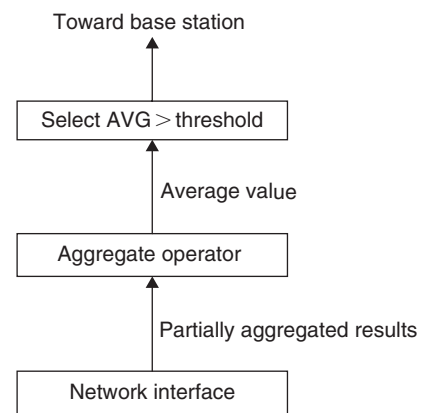

Figure 8: Query handling in Cougar: The leader node gets all of the readings, calculates the average, and, if greater than a threshold, sends it to the BS (Yao and Gehrke 2002)

Figure 9: Multiple levels in a convergecast tree (Yuan, Krishnamurthy, and Tripathi 2003)

to intermediate nodes based on their proximity to the BS is proposed in Yuan, Krishnamurthy, and Tripathi (2003) (see Figure 9). In this case, a node extremely close to the BS should wait more than the node that is far away from the BS. The presented mechanism broadcasts to all sensors the level of desired data accuracy and their hop distances to the BS. The sensors using this information compute their waiting times for data aggregation. The simulation results have confirmed that the proposed synchronization protocol can achieve the desired accuracy irrespective of the convergecast tree structure.

This approach is similar to the epoch-based approach of TAG (Madden et al. 2002a) and periodic per hop in Solis and Obraczka (2004). The only difference is that, in this case, the BS decides a level of accuracy depending on the application and sends a parameter to all of the nodes accordingly. The nodes receiving this parameter compute their waiting times for data aggregation. Therefore, the level of accuracy is adjustable.

Another approach to get different accuracy levels is used in Fjords (Madden et al. 2002b), which presents data aggregation mechanisms using query languages similar to SQL. To speed up the result of aggregated queries, Fjords

Figure 10: Pipelined aggregation in Fjords (Madden et al. 2002b). The time is divided into slots. At slot 1, the nodes at level 1 of the convergecast tree send their readings; at slot 2, nodes at levels 1 and 2 send their readings and so on. Thus, at each slot, an aggregated reading is received at node 1. The accuracy of the reading increases with the time.

suggests using a pipelined aggregation approach that continuously updates the aggregation result. The approach creates a convergecast tree initially by using broadcasting. The tree consists of multiple levels, and each level has sensors. When an aggregate query for periodic information retrieval is submitted, the nodes on the first level reply to the BS in a predefined time slot. In the next slot, the nodes on both the second and first levels reply. This continues until reaching the leaf nodes (see Figure 10, redrawn from Madden et al. 2002b). When a leaf node is reached, the BS will have replies from all of the nodes at all levels, leading to a robust and accurate result. This pipelined approach in Fjords provides multilevel accuracy, which is not the case in both TAG and Cougar.

Accuracy at the Link Layer

An interesting solution to improve the accuracy can be pursued at the link layer. Because this layer is responsible for improving reliability of the packet delivery, it can be exploited to improve the transmission reliability of the aggregated packets (Karl, Löbbers, and Nieberg 2003). This is especially important because aggregated packets have a lot of information and have required significant effort to create. If they are not recovered well enough, this may cause a significant degradation in the accuracy of the received information at the BS.

Therefore, the approach in Karl, Löbbers, and Nieberg (2003) is to try to assess how much effort to expend in deciding on different options of error correction at the link layer, depending on the capacity of information carried out by the data packet. For instance, if it is an aggregated packet, more sophisticated techniques such as *forward error correction* (FEC) or *automatic repeat request* (ARQ) can be employed before the transmission of the packet at the link layer. Although this sophisticated mechanism can increase data accuracy at the BS, it can also increase energy consumption of the sensor nodes. Therefore, depending on the application and the amount of information that an aggregated packet carries, a decision about how to reliably transmit the packet to the BS should be made. This is an interesting research challenge that creates a trade-off between energy and accuracy. Note that this problem is independent from the problem

of adjusting waiting times, which also affect the accuracy. The solution to this problem will be complementary to that problem.

SECURITY-AWARE DATA AGGREGATION

Most of the research on data aggregation in WSNs has assumed that all of the participating sensors and base stations are honest and trustable. However, sensors and other powerful nodes within WSNs can easily be compromised by physical tampering and other mechanisms. In such cases, the aggregation mechanisms should be resilient enough to handle the attacks initiated by those compromised nodes. Although the type of these attacks may differ, a typical attack related to data aggregation is to send false reports to the BS so that it will infer wrong results. Most of the protocols that will be described in this section deal with this problem. We discuss and compare the different solutions.

We also discuss the approaches that propose aggregation mechanisms for data that are encrypted or signed. This is extremely important because confidentiality in sensor communications will be a standard in future protocols. However, no aggregation is possible with encrypted data unless decryption is performed. Obviously, this offsets the energy gain through aggregation, so solutions are needed to perform data aggregation under confidential communications.

Data Aggregation under Compromised Sensors

To achieve secure and reliable data aggregation, security mechanisms that prevent the user from making false decisions at the BS are needed. *Secure information aggregation* (SIA) (Przydatek, Song, and Perrig 2004) is known to be the first work that considers security in data aggregation for WSNs. The work provides a security framework for developing algorithms for computing several aggregation functions such as, max, min, median, and sum, even though the aggregator or a fraction of sensor nodes are corrupted. The framework labeled *aggregate-commit-prove* has three steps. First, an aggregator node (other than the BS) collects the data from the sensors

Figure 11: Merkle hash tree creation (Przydatek et al. 2004). A hash is computed by concatenating two hashes from the children of a node.

that are authenticated. Second, the aggregator computes the result based on the received and authenticated data. Finally, it transmits the result along with a correctness proof to the BS.

The proofs are created through *Merkle hash trees* in which a hash is computed by concatenating two hashes from the children of a node as seen in Figure 11, which is redrawn from Przydatek, Song, and Perrig (2004). By checking the correctness of the proof, the BS can conclude whether or not the aggregator is cheating. This work provides an algorithm for the computation of each aggregation function, including median, average, count, maximum, and minimum.

In this Merkle-based tree approach, the formed tree is a binary tree in which only the leaf nodes generate data.

Recently, a similar but more flexible *secure hop-by-hop data aggregation approach* (SDAP) was proposed by Yang et al. (2006). SDAP logically determines groups of sensors within a convergecast tree and applies the idea of the Merkle hash tree on these groups through the BS. Thus, the tree can be arbitrary, allowing the intermediate nodes to aggregate their own results. For each group, a leader performs the aggregation and sends the result to the BS along with the proofs obtained through message authentication codes. The BS collects results from all of the groups and then evaluates their authenticity. Once this is done, the BS employs an outlier detection algorithm to eliminate the outliers from the received data. Based on the outcome of the outlier-detection algorithm, any suspicious groups are identified. In that case, those groups are asked to attest to the validity of their aggregates. If a group under attestation fails to support its earlier aggregate, the BS will discard this aggregate. SDAP calculates the final aggregate over all of the group aggregates that are either normal or passed the attestation procedure.

The same problem has also been studied in Du et al. (2003), who named it *witness-based aggregation* (WBA). The proposed approach selects some witness nodes to monitor the aggregation process. In addition to witness nodes, a data aggregator node is assumed that transmits the result to the BS. Each witness node is responsible for computing the aggregated result, getting a message authentication code of the result and forwarding it to the aggregator node. The aggregator node along with the result it has received from the sensors should transmit the proofs (i.e., message authentication codes from witnesses) to the BS. The BS can check the proofs and determine whether the aggregated results are correct as seen in Figure 12 (redrawn from Du et al. 2003). If there are

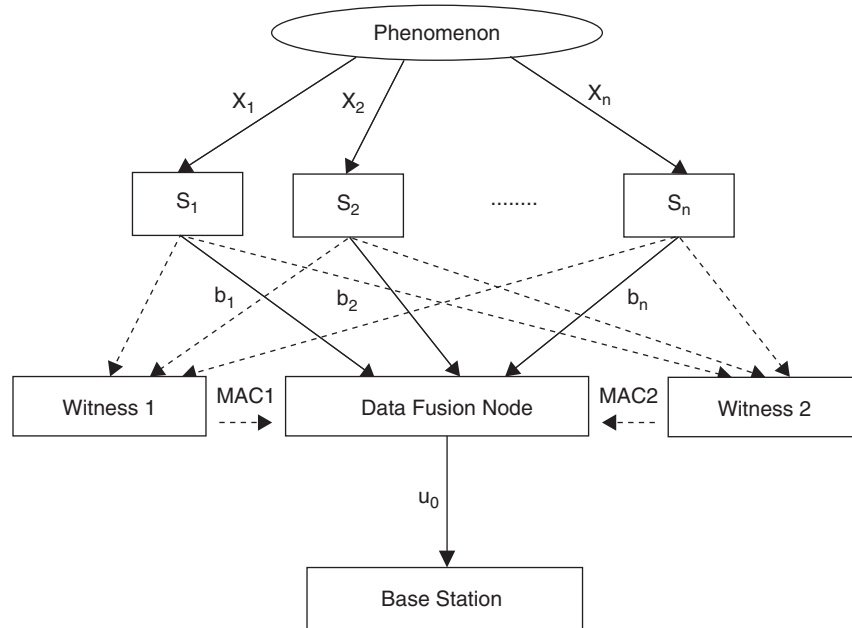

Figure 12: Verification by two witnesses and an aggregator (Du et al. 2003). Witnesses 1 and 2 also perform the aggregation from nodes S_1 to S_n , creating a message authentication code of the result and sending it to the data fusion node. All of the results are then sent to the BS by the data fusion node.

incorrect results, the BS can contact one of the witness nodes to receive the correct result.

Note that the approach summarized here is similar to SIA. The only difference is that WBA additionally employs witness nodes to double perform the result computation. In fact, both approaches utilize the same idea of using one-way hash functions in sensor nodes to relay the results to the BS. Although MAC computation is used to create proofs in WBA, Merkle-based hash trees are used in SIA to verify whether the aggregators are cheating.

Yet another approach called *secure aggregation* (SA) to the same problem is discussed in Hu and Evans (2003). In this case, however, there are neither aggregators nor witness nodes as opposed to SIA and WBA. Rather, the proposed solution in SA involves something called *delayed aggregation and authentication* in order to prevent intruders or compromised nodes from changing the result at the BS. Delayed aggregation suggests that the aggregation of data at a parent node will not be performed but forwarded to the grandparent as is. The grandparent will, however, perform data aggregation and authentication. The main idea of aggregation at the grandparent is to be able to detect the bogus data coming from the possibly compromised nodes that are close neighbors (i.e., child and parent). For example, in Figure 13, nodes A and B send their IDs, data R_A , R_B , to node E with a message authentication code of the data. E then forwards this information along with the message authentication code of the aggregated data (R_A , R_B) to its parent G. G finally performs aggregation of R_A and R_B , and hence can verify its correctness by computing its message authentication code and comparing it with the one it has.

In fact, SA uses MAC computation as done in WBA for performing authentication, but it is not performed at each level of the tree. Therefore, it is not clear whether it is as secure as WBA unless an experimental evaluation is made. Although this is lacking in SA, an analytical cost of the proposed protocol is computed to show that the protocol significantly reduces energy and introduces little overhead when compared to insecure aggregation.

In all of these approaches, all of the sensed data are sent from the source sensor to upper-level nodes and data aggregation is performed at the upper levels. To further

eliminate unnecessary redundant transmissions from the source sensors, ESPDA (Çam et al. 2006) has been proposed to transmit the representatives of the data called *pattern codes*. A pattern code is defined to represent the characteristics and summary of the sensed data. This is especially useful for the sensors with multiple sensing units. To generate the pattern codes, the cluster-head of the sensors generates a pattern seed that is a random number and broadcasts in encrypted format. Note that the paper considers a clustered architecture in which a sensor is randomly picked as the cluster-head for a period of time. Each cluster-head aggregates the data and sends it to the BS. Therefore, initially asymmetric keys are distributed to sensors and the cluster-head to perform encryption and decryption using the blowfish algorithm.

The idea is to detect redundancy by just looking at the transmitted pattern codes at the cluster-head. In addition, before sending the pattern codes, each sensor exchanges its sensing region information with other sensors within its neighborhood. During this process, if there are overlapping regions, some of the sensors are forced to go to sleep because their data would be redundant. Once the redundant pattern codes are detected at the cluster-head, only distinct sensors are picked to send data in encrypted form to the BS through the cluster-head. Performance evaluations have shown that ESPDA can reduce the bandwidth usage by 50 percent when compared to a conventional data aggregation algorithm without compromising the security of the system.

Aggregation of Encrypted Data

An extremely interesting security problem is the aggregation of encrypted data without decrypting it (Castelluccia, Mykletun, and Tsudik 2005; Girao, Westho, and Schneider 2004). In fact, the research on this problem is quite necessary because most of the communication among the sensor nodes is envisioned to be encrypted and authenticated in future applications. In such deployments, decrypting the data, performing the aggregation, and reencrypting the data for transmission will not only be highly inefficient in terms of energy consumption but

Figure 13: Delayed aggregation in a sample tree (Hu and Evans 2003). G performs aggregation of A, B and C, D and compares the results with the MACs of aggregated data coming from E and F to verify the correctness.

will also generate unnecessary traffic, decreasing the available bandwidth.

If the aggregation function is known a priori, one solution to this problem is to be able to perform the aggregation with encrypted data; this process is called *homomorphic encryption*. Using this approach, a different scheme is needed for each aggregation function—for instance, performing encrypted addition and average require different algorithms. Castelluccia, Mykletun, and Tsudik (2005) study these kind of algorithms, including schemes for addition, average, and variance. Girao, Westho, and Schneider (2004) present a different algorithm for computing the average. The main issue in this research is to come up with light-weight schemes that will not bring a computationally expensive load to the sensor nodes. However, this type of aggregation may not work for all functions. For example, it is not possible to eliminate data redundancy by just looking at the encrypted data.

CONCLUSION

In-network data aggregation in WSNs has attracted a lot of attention from the research community because of its potential for reducing the energy consumption of severely constrained sensor nodes. In this chapter, we described how in-network data aggregation is performed and summarized how it impacts energy, latency, accuracy, and security by discussing several approaches.

Although the summarized approaches solved many interesting problems and contributed to the development of WSNs, there are still many open issues. The following are possible future research issues to be investigated.

- We envision that the design of query languages for WSNs in order to handle aggregate queries will attract more research in the future. This is especially critical for the design of high-level programming languages for WSNs—that is, *macroprogramming*. Providing acceptable latency and accuracy along with energy efficiency should be included in query language designs. New query languages that can support specification of these metrics in the queries for sensor databases are also needed. This definitely necessitates collaboration between the networking and data management communities.
- Delay-constrained data aggregation has not been given enough consideration. Therefore, efficient heuristics for solving the *delay-constrained MST problem* are needed to provide delay guarantees for data aggregation. Another concern that will affect the heuristic is the type of aggregation function used. For complex aggregation functions such as median and histogram, there will be additional delays for computation that may affect the end-to-end data latency received at the BS.
- The problem of link layer recovery for aggregated packets mentioned in Karl, Löbbers, and Nieberg (2003) can be another interesting future challenge that may promote research into error control and correction with energy trade-offs. Because aggregated packets carry more information, it may be wise to handle their link layer transmissions with more sophisticated error-correction algorithms. This can be adjusted based on the location of the packet in the convergecast tree.
- An interesting technique to improve accuracy without affecting energy usage can be using adaptive sampling (Willett, Martin, and Nowak 2004). In this case, a small representative subset of sensors is picked to respond to a query. In such cases, performing data aggregation will require careful treatment because not all of the sensors are involved. Thus, investigating the relation between in-network data aggregation and adaptive sampling is an interesting research direction.
- Some performance comparison studies are needed to assess the best approach for secure data aggregation (such as SIA, WBA, and SA) in terms of energy, delay, and accuracy when compromised nodes or aggregators falsely contribute to the aggregated results.
- The data aggregation for multimedia data in wireless image and video sensors is a completely new area that requires considerable research (Kumar et al. 2003). Multimedia data aggregation is challenging because of the limited power the sensors have. Currently, the aggregation is performed only on images by eliminating temporal redundant objects. Video data aggregation has not yet been accomplished because of the additional challenges presented by delay and jitter (i.e., delay variation) requirements.
- In heterogeneous WSNs, data aggregation and computationally expensive operations are planned to be performed in special nodes that are assumed to be more powerful than sensors. Therefore, an interesting research problem for heterogeneous WSNs is to determine the number of aggregators and optimal locations for such nodes for best performance in terms of energy, delay, and accuracy.
- All of the discussed approaches in this chapter assume a single BS. In some setups, multiple BSs are employed. In this case, a research challenge is determining how to perform data aggregation in multiple-source, multiple BS WSNs. Xue, Cui, and Nahrstedt (2005) is an initial attempt to consider this problem; it proposes an algorithm to combine multiple convergecast trees into a data structure named *aggregation forest*. However, this solution is based on an updated Dijkstra's shortest-path algorithm that does not provide a lot of opportunities for data aggregation. New approaches are needed that will consider other heuristics such as CNS for aggregation forests.
- Finally, it would be interesting to quantify and compare the affects of data aggregation with data caching on delay, accuracy, and so on in WSNs. Nodes could cache and reuse previously retrieved data from neighboring nodes to quickly respond to repeated queries, thus reducing delay and saving network bandwidth. They could also save the results of queries or computations for additional energy savings and reduced delay. However, accuracy of the results could decrease as a trade-off, therefore it would be an interesting future work to investigate the applicability of these techniques to different scenarios.

GLOSSARY

- Automatic Repeat Request (ARQ):** Mechanism for handling errors at the link layer.
- Base Station:** Node that collects data from the sensors.
- Convergecast Tree:** The reverse of a multicast tree in which a node receives data from multiple nodes.
- Heuristics:** An algorithm that tries to get solutions close to optimal in a reasonable amount of time.
- In-Network Processing:** The operations performed when data packets are traveling in the network.
- Message Authentication Code:** A tag that is computed by applying a function with a key to a message for authentication purposes.
- Network Topology:** The graph created with sensors as the vertices and the links among them as the edges.
- Query Language:** Computer language to create queries for databases (e.g., sensor databases).
- Weighted Fair Queuing (WFQ):** A packet-scheduling mechanism that uses multiple queues to serve to different classes of packets in a weighted round-robin fashion.

INTRODUCTION

A convergence of technology trends is changing the operational and design characteristics of radio devices. The first of these technology trends is software-defined radio (SDR). SDRs allow much of what was previously done with application-specific hardware, such as signal processing, to be accomplished in software, whereas traditional radios have fixed designs and are often implemented solely in hardware (e.g., application-specific integrated circuit [ASIC] technology; see Figure 1). Next is cognitive radio (CR) technology, wherein the device can autonomously

make decisions about its operation in response to environmental changes (e.g., interference) or changes in the required capability of the device (e.g., application requirements). Such capabilities will enable future radios to vary waveforms and frequencies within their hardware constraints, as well as reconfigure how their network protocols operate. It should be mentioned that the distinctions among these technologies might appear blurry. For example, although it is possible to build a CR on top of an SDR—a cognitive/software-defined radio (C/SDR)—it is certainly not necessary. In other words, one could develop a CR that is not built on top of a software-defined radio. One should also understand that any of the technologies (SDR, CR, or C/SDR) could be the basis of a platform that offers frequency agility. Frequency agile devices can change how and where they operate within the radio spectrum by moving among a set of frequency bands.

An SDR can be described as a transceiver in which much of the physical layer is programmable, allowing the device to be reconfigured to meet changing needs. Integral to this ability to reconfigure is the support for various modulation schemes, frequency adaptation, and portable waveforms. The International Telecommunications Union–Radiocommunications (ITU-R) defines an SDR as “A radio in which the RF operating parameters of frequency range, modulation type, and/or output power can be set or altered by software, or the technique by which this is achieved” (ITU-R 2004). Higher up the network protocol stack is the ability to adapt the medium access control (MAC) and routing capabilities, although this higher-layer functionality is generally not considered part of an SDR. The foundations of SDR are rooted in a collection of hardware and software, with the objective to move a significant part of the radio’s processing from the analog to the digital domain and from the hardware to the software domain, thus affording the flexibility, interoperability, and efficiency required. The ideal SDR is one that allows all

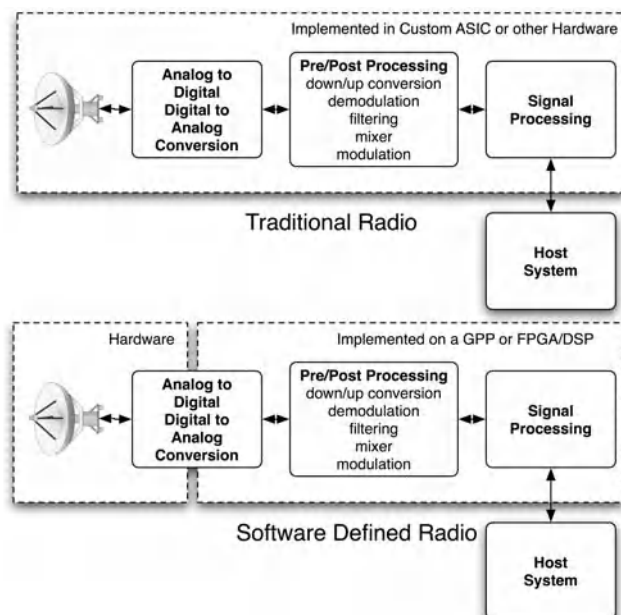

Figure 1: Traditional versus software-defined radio

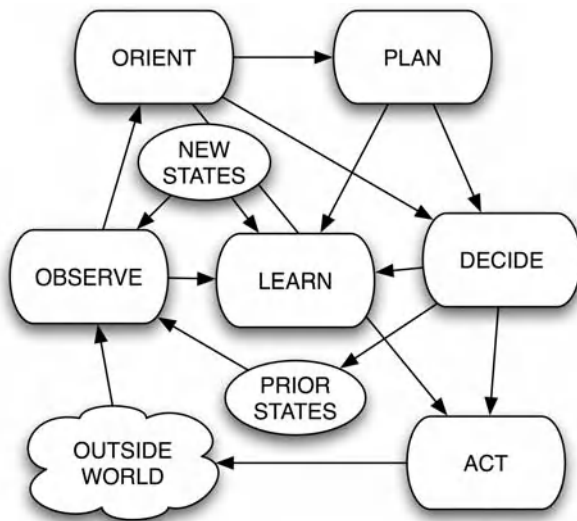

Figure 2: Simplified cognition cycle (Mitola 2000)

signal processing to be done digitally in software (Bose 1999), although this might not be a reasonable approach given the limitations of input/output and computing bottlenecks.

In 1999, Mitola (2000) coined the term *cognitive radio* to represent a device that is aware of its environment and can adapt its operation in complex ways. At its core, a CR can sense, adapt, and learn from its surroundings. Mitola developed a comprehensive cycle of cognition for a CR, a simplified version of which is shown in Figure 2. In the chart, he describes the possible steps that a CR might take in assessing its environment; these include observe, orient, plan, learn, decide, and act. Various complex relationships can be defined among these steps.

Software-defined and cognitive radio can combine into a highly flexible device, one that is aware of its radio frequency environment. These C/SDRs are ideally suited for the creation of frequency agile radios, in which the device can autonomously select operating parameters in a way that improves access to available spectrum and thereby could contribute to improvements in spectrum utilization (we refer to this as *dynamic spectrum utilization*). One can envision an advanced wireless network that dynamically allocates and reallocates spectrum or dynamically reconfigures itself in response to changes in policy and environmental conditions. This type of flexible spectrum usage raises interesting issues regarding the role of primary users (i.e., incumbent spectrum users) and secondary users (i.e., new users of the spectrum). For example, to what extent is a secondary user allowed to interfere with primary users, and how do we even define such interference? This level of flexibility in a wireless platform not only allows us to reexamine the problem of spectrum utilization, it also offers the ability for devices to cooperatively configure themselves to support the quality-of-service demands of applications running across the network.

One might appropriately ask whether frequency agile radios represent anything new. In some ways, they do not—there are many systems and devices that incorporate some subset of this technology. Current second-generation

cellular technology incorporates sophisticated transmit power control. Even a typical 802.11 card supports many of the requirements of a frequency agile device: they rely heavily on software to operate (although not at the physical layer); they can sense their environment (through listen-before-talk [LBT] and channel sounding); and they can alter their frequency parameters (within a set of channels). However, they do all of these things in a rather rudimentary manner. One could also argue that even conventional hardware radios have some of these characteristics, although, they are much more limited in terms of their ability to dynamically alter their operation and have certain physical limits in terms of their potential for reconfiguration (simply because of the physical and cost constraints of adding hardware to support additional features). The configurations of such conventional devices are generally set during the design phase, and there is little to no ability to alter this configuration after development. Finally, conventional hardware radios are developed through baseband design methods, whereas SDRs overlay a software architecture on top of this model. This ability to alter the design of the device is powerful in that it offers the ability for upgrading, patching, and altering a device that has already been deployed.

Taxonomy

In this section, a taxonomy for defining future radio technology is presented. At one end of the taxonomy there is the traditional radio, in which specific functionalities are determined during initial design and are generally implemented in hardware. Next in the taxonomy are SDRs, which are functionally equivalent to their analog predecessors; however, these devices are implemented on field-programmable gate arrays (FPGA), digital signal processors (DSP), general-purpose processors (GPP), and/or other programmable processors. Such devices shift hardware-based functionality and control to software. The rise of SDR began alongside the transition from radios that used highly specialized DSP hardware to those that use GPP and software (Tennenhouse and Bose 1995). In addition to the GPP, SDR has driven parallel advancements in other radio components, including new antenna, amplifier, and filter technology. Advancements in this area also fueled a need for analog-to-digital converters that were cheaper, faster, and more power efficient. There are a host of problems in specifying computer architectures that are able to meet the demands of an SDR. Furthermore, cost, power, size, and weight limitations might initially influence the capacity and design of SDR technology.

At the other end of the taxonomy are radios that incorporate computational intelligence. These *cognitive* radios will be able to sense, learn, and act in response to changes in their environment. The ultimate cognitive radio will be able to autonomously negotiate and propose entirely new optimized protocols for use in the networking environment. In other words, this technology would allow devices to dynamically reconfigure their operational parameters to enhance performance metrics such as throughput, bit error rate, or delay. It is important to note that a cognitive radio could be built on top of either a traditional radio or a software-defined radio. Table 1 presents this taxonomy.

Table 1: Taxonomy of Traditional, Software-Defined, and Cognitive Radios

Traditional Radio	<ul style="list-style-type: none"> • Specific functionalities determined during initial design (limited upgradeability) • Design based on traditional design models • Implemented in hardware (e.g., ASIC-based technology)
Software-Defined Radio	<ul style="list-style-type: none"> • New functionality can be added through software updates (enhanced upgradeability) • Design largely based on software design models • Implemented on programmable processors
Cognitive Radio	<ul style="list-style-type: none"> • Required functionality can be determined and negotiated (intelligent upgradeability) • Combines software design with reasoning techniques • Implemented in flexible hardware and/or software

Motivation

Among the many reasons for developing frequency agile radios, the two strongest motivations are (1) for purposes of efficiently accessing spectrum, which is perceived as a scarce resource, and (2) for improving interoperability of wireless devices. Around the world, various government agencies and industry players have realized that current radio technology will not adequately meet the demands of the future. A large amount of funding has been directed at solving the interoperability problems between military components. Changes in funding and grant solicitations also mark a shift in research focus from one centered on achieving interoperable radios to one focused on highly adaptable, flexible, and reconfigurable communication devices and algorithms.

A common thread in both the research and funding shift is increased efficiency in our use of the available radio frequency (RF) spectrum. A 2005 study undertaken in the Atlanta metropolitan area reported that less than 7 percent of the available spectrum was being utilized during the several months that the study was conducted. Additionally, 77 percent of the spectrum in this area was completely unused (Petrin and Steffes 2005). However, observed availability does not mean that the spectrum is

not “owned” by some agency or corporate body. Indeed, it doesn’t even mean that it is not being used (e.g., radio astronomy bands, where earth stations simply listen for RF signals from outer space).

The scarcity of spectrum is influenced by both technical and regulatory practices. However, ownership issues aside, it is clear that there is a vast amount of unused and underutilized spectrum. Figure 3 presents a graph of spectrum occupancy from 1.2 GHz to 2.2 GHz in a large European city. Universal mobile telecommunications system (UMTS) and global system for mobile communications (GSM) services in the 1.8–1.9 GHz range are the major occupants of the band; note the low occupancy in the remainder of the band. The area between 1.2 and 1.8 GHz, with the proper technical and regulatory support, would be ideally suited for operating a frequency agile device. Initial findings show that even simple noncooperative sharing techniques can offer significant improvements, with cooperative protocols offering an order of magnitude increase in available spectrum (Horne 2003).

Much of the resistance to adopting emerging wireless technologies stems from the huge cost involved when removing and replacing existing infrastructure with technology that can support the new standards (Bose 1999).

On the other hand, a C/SDR platform may be able to adapt to new standards by downloading and installing new software. The flexibility inherent in the C/SDR also allows it to adapt to changes in policy. The recent focus on homeland security, in light of the ineffective use of the emergency bands, has given impetus to many of the scenarios that illustrate the promise of C/SDR. One could imagine a government agency implementing a change to local spectrum policy in response to a disaster. Updates to policy, when acted on by a C/SDR network, could affect reallocation of spectrum to support increased demand during the emergency. Work in the C/SDR space has also been directed at improving interoperability among radio devices. The pressure for this interoperability is significant within the U.S. military (where each service uses different and incompatible radio technology) and by public safety entities such as police, fire, and ambulance.

PRIOR WORK IN SOFTWARE-DEFINED RADIO

This section is focused on providing an overview of the research in software-defined radio. The work encompasses Department of Defense (DoD) efforts, which are focused on waveform portability and radio interoperability, as well as work done in the private sector, which focuses on solving input/output (I/O) and computation problems associated with moving traditionally analog or custom ASIC components and processes to a general-purpose processor. Figure 4 provides a timeline of some of the major SDR and CR developments, and the following sections provide an overview of prior work within this space.

SPEAKeasy

SPEAKeasy was a joint program of the U.S. Air Force, Army, Navy, and Defense Advanced Research Projects Agency (DARPA) that arose from interoperability problems that were experienced during the Grenada conflict (Lackey

and Upmal 1995). SPEAKeasy was to develop a radio that would allow multiple waveforms at multiple frequencies to coexist in the same physical unit. Additionally, it would provide the ability to communicate with legacy radios. Along with basic research and development, the production schedule included prototype demonstrations. The initial prototype, shown in 1995, demonstrated multiband operation, programmability, and bridging. Development and prototype demonstrations continued until late 1998. Many key ideas and concepts for SDRs arose from the development of this system. There was a need for a software architecture that would decouple the radio hardware from the software framework. This would allow hardware to advance independently of the software architecture. Additionally, there was a need to capitalize on commercially available products because the DoD could no longer afford to fund proprietary solutions. To ease maintenance of the radio, the developers saw a need for over-the-air updating of the radio software. SPEAKeasy was nominally one of the first software radios in operation.

Joint Tactical Radio System

The SPEAKeasy project was transformed into a fully funded DoD project soon after its last demonstration in 1998. The Joint Tactical Radio System (JTRS; n.d.) was founded on concepts that were a part of the SPEAKeasy project and a vision document within the military (Joint Vision 2010/2020). The program funds the production of a host of radios ranging from inexpensive terminals with reduced waveform support to multiband/mode/channel radios that support advanced narrowband and wideband capabilities. These high-end devices will also include integrated computer networking features. The primary goal of JTRS is to develop a family of radios that is able to meet expanding bandwidth requirements and is interoperable, affordable, and scalable. The program managers felt that the only way to meet these objectives was to require that the radios conform to open physical and software architectures. JTRS has experienced significant difficulties in meeting program goals and cost constraints.

Figure 4: Timeline of software-defined and cognitive radio developments

A key component of the JTRS is the Software Communications Architecture (SCA). The SCA is an open architecture framework that utilizes the Common Object Request Broker Architecture (CORBA) to dictate the structure and operation of the radio. Critical components of the architecture are standards for loading waveforms, running applications, and system integration. The SCA Hardware Framework (SCA/HW) dictates minimum specifications for hardware devices. These two frameworks ensure that software written to the SCA will work on compliant hardware. Although this approach has some backing, there are shortcomings. First, it has grown into a complex and heavy design. Second, it does not offer any capabilities for the emerging needs of a dynamic system such as a CR. Finally, it is not well oriented toward lightweight implementations. The SCA is currently at version 3.0 and has been adopted as a standard by the Object Management Group (OMG).

Rapidly Deployable Radio Network

The Rapidly Deployable Radio Network (RDRN) was another early SDR (1994–1999) that was specifically designed to address problems when implementing mobile, rapidly deployable, and adaptive wireless communications (Evans et al. 1999). Researchers created a high-speed asynchronous transfer mode (ATM)-based wireless communication system that was adaptive at both the link and network layers, allowing rapid deployment and response in a changing environment. Their concept of operation was to deploy a backbone of switches that would automatically configure into an appropriate topology, enabling users to access the backbone via a cellular-like architecture. The RDRN project incorporated digitally controlled antenna beams, programmable radios, adaptive link layer protocols, and mobile node management. The combination of the network layer routing protocol and directional phase array antenna was the basis for the adaptive point-to-point topology algorithm. Additionally, at the data-link layer they were able to change modulation, frame lengths, and enable and disable forward error correction; however, project literature states that these are set at device program time. They concede that the next steps for the project would be to develop an algorithm that would run in the radio processor, enabling dynamic adjustments to power level, coding depth, antenna pointing, modulation type, and data rate.

Vanu

During the mid-1990s, effort was directed at realizing the transition from specialized hardware to GPP. Vanu Bose set out to demonstrate that it was possible to implement a high-data-rate, computationally intensive, real-time signal-processing application on a GPP. This effort formed the basis of his thesis and later launched his company, Vanu Inc. (n.d.). His doctoral work produced an SDR that was able to run on a general-purpose processor. In this work, he acknowledged that there are huge opportunities to improve wireless networking using SDR technology. He recognized that a radio that could adapt and change its operating characteristics in real time could significantly impact wireless communication. In November 2004, Vanu's software radio global system for mobile communications

(GSM) base station became the first device to successfully complete the Federal Communications Commission (FCC)'s certification process governing SDR devices. Mid Tex Cellular operates the first commercial deployment of this system. Vanu's Anywave GSM base station is capable of remote software updates, allows multiple standards to coexist on one network, and has the potential to decrease cellular maintenance budgets by as much as 20 percent (Whickham 2005).

End-to-End Reconfigurability

The end-to-end reconfigurability (E2R; n.d.) project is among a host of international efforts to realize the potential of SDR. The E2R project aspires to develop designs and prototype systems that focus on the end-to-end perspective. The project, now in its second phase, is focusing on producing platforms that are accessible across the device and user spectrum, ranging from advanced cellular handsets for the consumer to advanced spectrum management tools for the regulator.

Summary

This early research is important because of the progress made in the realization of the SDR. The research provides valuable insight into the design and implementation of future platforms. Additionally, the systems and research covered in this section provide historical perspective and bolster the case for intelligent processing on a software radio. Much of this early work in SDR set the foundation for, and in some cases directly called for, research to begin in creating intelligent radio systems. Generally, the research and development in software-defined radio has been characterized by the building of systems to solve specific problems. The DoD efforts are focused on waveform portability and radio interoperability. The RDRN project was centered on mobile and rapidly deployable disaster response communication. The work done by Vanu Bose focused on solving I/O and computation problems associated with moving traditionally analog or custom ASIC components and processes to a general-purpose processor.

PRIOR WORK IN COGNITIVE RADIOS

Scientific and commercial interest in cognitive radio stems from its goals: to increase access to available spectrum, and improve interoperability and reliability through adaptive and efficient use of spectrum. In terms of spectrum policy (or the rules that govern spectrum usage), CR offers the ability to intelligently manage access to the spectrum. The popularity of CR in the research community is being fueled, in part, by this goal. Other research focuses on the development of algorithms to exploit more general networking goals. Research has only begun to tackle the issues raised when a system of these highly reconfigurable SDR platforms is acting in concert.

Genesis

Mitola described how a cognitive radio could enhance the flexibility of personal wireless services through a new language called the Radio Knowledge Representation

Language (RKRL; Mitola 2000). RKRL was a language for describing the features and capabilities of a radio. Mitola describes it as a set-theoretic ontology of radio knowledge. Mitola's doctoral dissertation was presented in May 2000, and his research resulted in the development of an architecture for CR and the formulation of a set of use cases for computationally intelligent radios. Additionally, he developed a simulation environment in order to test the viability of RKRL. The simulation focused on natural language processing in a CR. The experience he gained while conducting this simulation led to the formulation of his architecture for CR. This work set the stage for future research in the area by providing a description of what it means for a radio to incorporate computational intelligence. Mitola also described nine levels of operations that relate to the functionality of a cognitive device (Mitola 2000). These levels ranged from basic preprogrammed devices (Level 0) to devices that could dynamically create new protocols based on the environmental conditions and communication requirements (Level 8).

Algorithms for Cognitive Radio

Often the word *algorithm* causes one to envision a complex and involved solution to a problem. However, there are whole classes of algorithms that are simple, elegant, and applicable to C/SDR. Algorithms of this sort are members of a class of direct methods for tackling problems associated with the design and implementation of a C/SDR. Some of the more well-known approaches are the LBT algorithms, all variants on the notion that the sender should sense (listen) to the medium before attempting to access it (Metcalf and Boggs 1976; IEEE Standard 802.11 1997). Another technique, transmit power control, seeks to minimize the transmit power used in communication among nodes to decrease the overall interference. Dynamic frequency selection (DFS) algorithms have seen a corresponding rise in interest in the literature coincident with the increase in popularity of C/SDR. Horne (2003) details four common approaches:

1. Channel availability check. Before starting a transmission, the sender must monitor the channel for a defined period of time to determine whether a signal is present (LBT).
2. In-service monitoring. The radio device must continually listen on the channel by searching for signals between transmissions.
3. Channel abdication. On detection of a signal, the device must stop transmitting and move to another channel.
4. Channel non-occupancy. If a channel is occupied, the sending device will not utilize the channel for a set time period.

These techniques are present in common everyday devices like many cordless 900 MHz phones. These phones sense interference on a channel and switch to another to obtain a clear signal.

Game theory relies on a mathematical model of an interactive decision process. In C/SDR, the network of radios is bounded by actions wrapped in a mathematical model. The game theorist uses the analytical power of game

theory to guide his or her algorithmic decisions. There has been some research done in applying game theory to C/SDR; this work is concerned with bounding and qualifying potential algorithms according to a game that approximates the function of a CR (Neel, Reed, and Gilles 2004). The authors contend that game models will give insight into algorithmic complexity. This approach to bounding potential algorithms in a defined game space is interesting; however, it does not appear to offer direct insight into what the underlying algorithm should be. Other work in this area includes the application of machine learning or similar techniques to the problem of decision making within CR networks. For example, Rieser (2004) describes a biologically inspired cognitive engine that employs a genetic algorithm to optimize the robustness of the radio network. He developed a cognitive model and architecture that was able to operate in unforeseen communication environments and recall past successful configurations via memory.

A broad range of potential algorithms exists for controlling CRs. LBT and DFS algorithms are important because they are simple algorithmic examples that afford huge returns. Nevertheless, they suffer from one-dimensionality in that they focus on interference-free channel access alone. Investigation of simple algorithms like LBT across multiple dimensions could yield promising results. A collection of simple algorithms acting in concert could drastically outperform individual component solutions. The game theoretic approach is useful if one is interested in characterizing potential algorithms in a game space; however, the algorithm behind this characterization remains a black box. The work in genetic algorithms demonstrates that cognitive processes can successfully reconfigure in response to changing channel conditions with success in achieving the CR's goal (Rieser 2004).

Beyond these described methods, numerous other techniques—such as Markov models, neural nets, expert systems, and fuzzy logic—could be used to implement a CR. The question remains as to which of these will actually be applied in a real system.

DARPA XG

The DARPA Next Generation (XG) Communications (n.d.) Advanced Technology Office (ATO) is the project management arm of a DoD project whose objective was to develop and demonstrate a prototype spectrum agile radio. They set a performance target of increasing spectrum utilization tenfold without causing harmful interference to primary/noncooperative radios. The project is addressing spectrum management difficulties associated with deployment and spectrum scarcity issues through development of devices and protocols for opportunistic spectrum access. In this scenario, a primary user should not experience interference when a secondary user attempts to access a band. One method for mitigating interference by the secondary user is to require the secondary to vacate the band and continually check for primary users. Much of the work in this area is dependent upon the development of highly sensitive detectors and the combination of individual and group sensing to determine the RF environment. This data will be combined with a variety

of additional information to assist the device in making scheduling decisions about how best to operate. Other sources of data could be derived from location, time of day, and databases containing pertinent data and policies on primary users. A Web Ontology Language (OWL)-based policy description will assist the decision process by providing rules and behaviors in machine-readable form. Combined, this information will indicate the spectrum “holes” that are available for the user.

A secondary objective of the program was to leverage and develop technologies that enable dynamic access to spectrum within constraints provided by machine-readable policies. Technology central to this goal includes adaptive MAC protocols, hardware-independent policy-based reasoning, and new waveforms. The policy engine operates by obtaining a set of policy conditions that might associate with a certain device, in a certain location, attempting to make use of a certain band. The policies will be expressed in extensible markup language (XML), and the engine will parse these policies to determine a limited set of possible operational conditions for the device. The device then determines how these might best be used to meet communication requirements. Each of these policies is authenticated, and its operation will be traceable. Ultimately, the goal is to provide a framework that describes the policy boundary for a device; then the device will be able to operate within these boundaries in a variety of ways. The architecture supporting this policy-driven operation is depicted in Figure 5.

Additionally, XG is pursuing the creation of a waveform that combines noncontiguous narrowband channels. These waveforms will respond to and capitalize on spectral vacancies in both time and frequency. As we move higher in the protocol stack, the system is able to adapt to future MAC layer protocols and algorithms. Here the difficulty lies in being able to maximize spectrum utilization while still allowing short-duration transient reallocations

without saturating the network with protocol overhead. The XG project’s objectives are addressed through theoretical work, simulation, and platform development.

Recent Work in Cognitive Radio Networking

Haykin (2005) provides a thorough overview of cognitive radios and describes the basic capabilities that a “smart” wireless device might offer. Others describe techniques for applying CRs to improve the coordinated use of spectrum (Berlemann, Mangold, and Walke 2005; Buddhikot et al. 2005). Sahai, Hoven, and Tandra (2004) describe some of the physical layer limits and limitations of cognitive radios, including the difficulties associated with determining whether or not a radio frequency band is occupied. Nishra et al. (2005) have implemented a testbed for evaluating the physical and data link layers of such networks. Additionally, Thomas, DaSilva, and MacKenzie (2005) describe the basic concept of a CR network and provide a case study to illustrate how such a network might operate. Weingart (2006) and Weingart, Sicker, and Grunwald (2006) looked at using statistical analysis of variance (ANOVA) as part of a technique called design of experiments (DOE), to inform algorithmic decisions about the most effective configuration of the C/SDR. This approach produces an analytical model for the CR, which can either predict radio performance given a configuration and/or identify those parameters that have the greatest effect on performance. It is also worth noting that the standards communities are actively focusing on cognitive radio (these efforts will be discussed later in the chapter).

CHALLENGES FOR FREQUENCY AGILE COGNITIVE RADIOS

The ability of frequency agile radios to sense radio frequencies and alter operational parameters such as frequency, power, modulation, beam direction, and link access protocol creates an opportunity whereby devices could autonomously decide how best to operate to improve their access to the radio frequency environment. However, assessing the radio environment is a difficult task—one that will require the development of new hardware and software, complex propagation assessment techniques, and complex information integration. It also will require the radio community to rethink what defines harmful interference. New certification and assurance techniques will have to be developed to assure that frequency agile devices won’t misbehave. To understand the need for certification, consider the problems that might arise if secondary user devices interfere with public safety and aeronautical users.

The hope is that such adaptive devices will (1) allow for open radio architectures, (2) take advantage of price declines in computing devices, (3) support novel methods for accessing the spectrum, and (4) reduce the custom nature of radio chip design. However, it is uncertain whether these devices might intentionally or inadvertently operate outside of their expected RF parameters. Reliability, security, and design issues also remain unresolved.

Among the most significant technical challenges for frequency agile cognitive radios (FACR) is the ability to detect whether a band is occupied and guarantee that

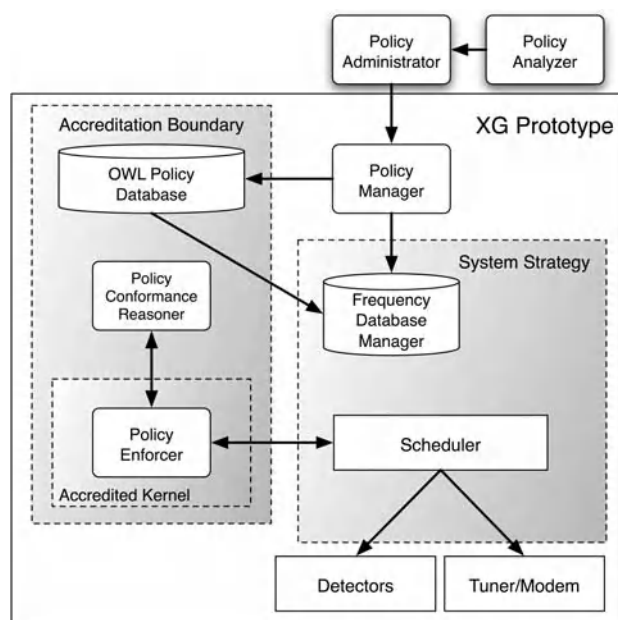

Figure 5: The DARPA XG architecture

secondary users will not interfere with primary users in that band. The development of high sensitivity detectors combined with supplemental information concerning the potential RF usage in a particular area (i.e., geo-location data, detection data from other local nodes, or possibly information contained in a database) will allow the cognitive part of the radio to determine whether a particular band is available for use. One unresolved issue is the development of appropriate measures for interference. Regulatory agencies and standards bodies are presently examining the issue of interference measurements. One proposed concept is that of an *interference temperature*. As described in the FCC Spectrum Policy Task Force Report (n.d.), an interference temperature offers a method for measuring and controlling the potential noise generation. A maximum interference level could be set for a particular RF band; if a secondary user can operate under that interference level, it would be considered as not causing interference in that band. The difficult issue is measuring and ensuring that the level is maintained.

Researchers tend to overlook some of the more esoteric concerns, such as those presented by regulators. A key component in the success of FACR is its acceptance as a fundamentally sound technology by those who regulate and control the radio spectrum. The technology that is proposed by researchers needs to be visible and understandable. That is, the regulators and the incumbents, those who have “ownership” of the radio spectrum, must be able to understand the mechanisms by which the radio operates and believe that it will perform as intended. Clearly, FACRs offer a new way of allocating spectrum to users. These advanced allocation techniques could allow national regulatory organizations to move from a rigid spectrum allocation mechanism to an interference-avoiding, open access model. Furthermore, the flexibility of such devices could facilitate the introduction of secondary spectrum markets. Such radios could (1) improve network performance, (2) improve spectrum utilization and availability, and (3) support novel interoperability designs. However, it is unclear just how the devices will be controlled and how interference might be determined in some of the potential operating environments.

As previously described, DARPA is funding an effort to create a human understandable radio policy language and associated computational engine. Additionally, regulators and incumbents must be comfortable with FACR technology before they will allow it to operate. This will likely involve certification of the algorithms and mechanisms that drive the device. For incumbent RF license holders, certification gives assurance that the FACR will not interfere in their transmission and that the devices operating in their RF space will relinquish their spectrum when required. There is also a large effort within the FCC to rework the current command-and-control model of spectrum allotment, assignment, and allocation. A transition to a legal structure that is more suited to advancements in radio technology, such as FACR and ultra-wideband, is under way.

Various national regulatory agencies are working on improving spectrum policy; notably the Office of Communications (Ofcom) in the United Kingdom, the Ministry of Internal Affairs and Communications (MIC) in Japan,

and the FCC in the United States. Ofcom (n.d.) recently released an in-depth analysis of C/SDRs and has been active in promoting novel approaches to spectrum management. In the United States, the FCC is actively seeking to improve the efficiency of spectrum management and is considering new regulatory models, including: (1) the development of secondary markets for spectrum, (2) the specification of receiver standards, (3) the consideration of FACRs, (4) exemptions for operation in TV bands, and (5) the development of an interference temperature (see www.fcc.gov, specifically FCC n.d., 2005; FCC Spectrum Policy Task Force Report n.d.). Together, these developments represent a fundamental shift in thinking about the potential to use spectrum in very new and exciting ways.

The significance of this type of regulatory reform must also be considered in the context of how regulatory agencies typically evolve, which tends to be slowly. The potential for change and the potential for new technology are quite substantial. This potential could be lost or delayed if the regulators find that the technology is not up to supporting these types of new spectrum models. Of concern to the policy makers are whether interference can be avoided and whether the device will operate as it should. The potential to interfere with primary spectrum users must be considered particularly because these incumbent spectrum holders have substantial lobbying influence. Furthermore, current national borders do not deal with the issue of spectrum sharing in their laws and enforcement methods; therefore, such efforts must consider international agreements.

Many of the software challenges in FACR are driven by Mitola's (2000) vision of the ultimate cognitive radio. He envisioned a system that was capable of reasoning about its environment. The system would draw upon past experience and current environmental conditions to make intelligent decisions about how it should reconfigure. Key components of realizing his vision were the radio's ability to sense, remember, learn, and act. In developing such technology, it will be important to understand how an FACR should sense the environment, determine what environmental inputs should be processed and when, and determine how environmental information is communicated to other systems in the network. Additionally, there are a host of problems that must be overcome in distributed systems, operating systems, and interaction with base hardware components. Research about how FACRs synchronize configurations, maintain communication during reconfiguration, and accomplish over-the-air software updates securely is also critical.

Another important area to consider is that of how trade-offs are balanced by the FACR in meeting its goals. The radio's cognitive engine will be driven by knowledge of its operating environment and its goals; additionally, the radio must cope with environmental information that will change over time. These changes in environment, goals, or networking conditions will force the radio to change its current operating mode, much in the way an operating system must respond to interrupts. For example, if a wireless link is riddled with interference, an FACR could react by changing its current default route to bypass the interference or enable forward error correction on the noisy link. It will be important to define and evaluate how the FACR is

affected by interrupts to its current operating mode. This analysis may reveal which interrupts require immediate, delayed, or no action.

Beyond physical layer adaptation, an FACR will allow for dynamic cross-layer adaptation. Work in the area of cross-layer optimization has typically focused on enhancing throughput, quality of service (QoS), and energy consumption (Goldsmith and Wicker 2002). However, these types of cross-layer optimizations tend to be limited in their application. In fact, most of the work in this area tends to focus narrowly on two layers, precluding unique solutions. In other words, they do not consider a broadly adaptive solution nor do they consider user-level requirements. Kawadia and Kumar (2005) have presented an interesting critique of cross-layer design; they warn that cross-layer optimization offers both advantages and disadvantages to the system designer. The dangers they discuss include the potential for (1) spaghetti design (i.e., complex, seemingly unstructured design), (2) proliferation problems, and (3) dependency issues. When dealing with complex systems—in which there are hundreds, if not thousands, of potential configurations—one will find that there is not a simple set of rules that can be universally applied. FACRs with a large number of configurations will require online evaluative methods to account for unintended interactions between the FACR's settings and the radio frequency environment (Weingart 2006).

The adaptive and dynamic natures of these systems lead to other interesting questions. It will be important to quantify the amount of time that a cognitive process can devote to computing a radio configuration, thus allowing characterization of the types of processing that can be done without negatively affecting communication. This line of research should also provide insight into what processing should be done in real time, off-line, or in the background. Another challenge is devising a set of metrics that can be used to evaluate and guide the design of the FACR's computational engine. The following metrics may be considered: goodput, latency, bit error rate, medium access delay, fairness, power consumption, spectrum utilization, and reconfiguration time. Also of interest is how a cognitive system will manage trade-offs in optimizing network performance and reliability.

For readers interested in working within the open source community on SDR, there is the GNU Radio Project (n.d.). This work particularly is focused on the development of software-defined waveforms. Work described in Weingart et al. (2005) and Doerr et al. (2005) focuses on the development of low-cost, adaptive MAC systems. By making these products reasonably priced, one lowers the threshold for engaging in experimental efforts as opposed to theoretical work.

Although they are not the focus of this chapter, there are numerous interesting problems at the physical layer to consider. Various physical layer issues are equally important to achieve flexible radios (e.g., the RF front end, the signal processing implemented in software, the analog-to-digital converters and processors, and the control mechanisms that put requirements on the network). One of the problems in creating a flexible SDR is that of developing a flexible RF front end. Interesting work is under way in developing a microelectromechanical system

(MEMS)-based antenna. Developing analog-to-digital converters that are appropriate for SDR systems will require changes to the sampling capability and the range of existing systems. Significant work is under way in the area of FPGA-based SDRs. Together, advances in these areas will have a significant impact on the realization of more flexible SDR platforms and therefore more flexible frequency agile radios.

STANDARDS

Before closing this chapter, it is worth mentioning the newly formed standards efforts that have responded to the development of frequency agile devices. Although a number of groups are working on standards relating to FACRs, this section briefly describes recent efforts undertaken by the IEEE Project 1900 Next Generation Radio and Spectrum Management Committee and the 802.22 Working Group on Wireless Regional Area Networks.

The P1900 (n.d.) group is broken into four subgroups; 1900.1 Definitions, 1900.2 Interference and coexistence analysis, 1900.3 Software Assurance, and 1900.4 Certification. P.1900.1 (n.d.) is working to develop standards terms and concepts for spectrum management, policy-defined radio, adaptive radio, and software-defined radio. According to their documents

This standard will provide technically precise definitions and explanations of key concepts in the fields of spectrum management, policy defined radio, adaptive radio, software-defined radio, and related technologies. . . . The document will also describe how these technologies interrelate and can be use in a wide variety of communication service environments to achieve new capabilities while at the same time providing mechanisms supportive of new spectrum management paradigms and spectrum access.

P1900.2 (n.d.) will “provide technical guidelines for analyzing the potential for coexistence or in contrast interference between radio systems operating in the same frequency band or between different frequency bands.” The goal is to guide the analysis of interference modeling and thereby improve the efficient use of the spectrum. P.1900.3 is seeking to develop conformance evaluation for SDR software modules. The purpose is to provide recommendations for the practices that will lead to compliance for adaptive devices. Much of this work will focus on the development of formal methods for evaluating a specific software design before the device is actually created.

IEEE 802.22 (n.d.) is looking at wireless regional area networks (WRANs) that could operate in the unused TV broadcast channels. 802.11h is looking at ways of improving the sharing of spectrum among 802.11 users. There are two basic ways that this is operating: dynamic frequency selection and transmission power control (TPC). DFS provides a means for selecting and using a certain spectral band to avoid interference. TPC allows for the reduction of interference and the saving of power by managing power on access points and devices in a network.

The International Telecommunications Union is actively looking at standards efforts in the CR and SDR space. Other standards efforts, including 802.11k, 802.11y, 802.16h, are also addressing aspects related to cognitive radios.

CONCLUSION

New radio technologies promise to redefine how we design and build radio platforms. The combination of SDRs with cognitive functionality will enable the introduction of frequency agile devices and bring about radically different mechanisms for managing and accessing radio frequency resources. This technology promises increased efficiency in spectrum use, flexible device design, and device interoperability. However, there are still a number of technical problems to resolve before this technology is ready to market. Among these difficult issues are signal detection, interference avoidance, and device assurance. Some of the more interesting and uncertain influences in this area have nothing to do with technology; rather, they depend on decisions from within the public policy and regulation communities. Additional research directions in the area of frequency agile technology can be found at Dynamic Spectrum Access Networks (DySPAN; n.d.), the Workshop on Technology and Policy for Accessing Spectrum (TAPAS; n.d.), and the SDR Forum (n.d.).

GLOSSARY

- Cognitive Radio:** A transceiver that can sense and autonomously reason about its environment.
- Cooperative Protocol:** A protocol wherein the communicating elements act to jointly enhance operation.
- Cross-layer Optimization:** A mechanism in which information from multiple layers of a protocol stack is jointly used to improve system performance.
- Dynamic Frequency Selection:** A mechanism that allows a transceiver to detect available spectrum, access and use that spectrum, and abdicate its use when necessary.
- Dynamic Spectrum Utilization:** A process of adaptively selecting frequency-operating parameters to optimize a desired utilization measure.
- Frequency Agile Radio:** A transceiver that can change the frequency bands in which it operates.
- Hardware Radio:** A radio that defines and possibly changes its capabilities through its hardware.
- Policy-based Reasoning:** A mechanism that relies on a set of rules to inform decision processes.
- Policy Engine:** An algorithm that includes policy-based reasoning as an input for selecting sets of viable operating conditions.
- Software-defined Radio:** According to the ITU-R (2004), "A radio in which the RF operating parameters of frequency range, modulation type, and/or output power can be set or altered by software, or the technique by which this is achieved."
- Spectrum Policy:** A subset of regulatory policy and one that defines the valid use of the spectrum or the intended direction for the use of the spectrum.

Transmit Power Control: The mechanism that allows for the adaptation of transmit power of a transceiver.

NEED FOR WIRELESS LOCALIZATION

In the face of the increased numbers of mobile computing devices, the emergence of wireless networking technologies, and the provision of high connectivity for mobile devices, a great interest in localization has arisen. Localization is actually a requirement that an agent under mobility or interacting with mobile components has to accomplish no matter whether the agent has wireless communication capabilities or not. Localization is the determination of the location of any wireless component based on some techniques of measurement. Localization applies to three objects: (a) the user as a whole entity, (b) the services as software resources on mobile computing platforms, and (c) the entities acting on behalf of users. Applications needing to track a mobile user may require the position of a user at different periods of time, while a user needing to access a service (e.g., a bank's ATM) may require the service of an application providing the location of the nearest access point. A Mobile Service Switching center in GSM systems may act on behalf of a mobile user who has roamed under its coverage (Nicopolitidis et al. 2003).

It is obvious that compared to fixed networks, wireless networks may suffer from a high bit-error rate, inconsistent quality of service, and inefficient bandwidth utilization. These drawbacks are more important when nodes are on the move. They make wireless localization a challenging task to achieve. On the other hand, because mobile nodes are expected to support different types of applications and services that may run in continuous time or in real-time, and provide different qualities of services to various types of traffic, wireless localization helps considerably, in mitigating these drawbacks. A clear illustration of this duality can be stated through the three following facts:

The first important impact of wireless localization is on resource utilization, because it can facilitate the allocation, control, and effective use of the resource.

In cellular networks, for instance, where a node can find itself under the radio coverage of more than one base station, localization may help it locate and choose the nearest base station. This helps three objectives: (a) the signal degradation can be avoided or reduced; (b) the radio frequencies can be allocated effectively; and (c) the node can preserve the life duration of its battery as it decreases its transmission power. Localization may also contribute to the enforcement of equitable sharing of resources within a network. An example of localization sharing is represented by the distribution of printing jobs, required by n mobile nodes. For this, a printing request issued by a node can be sent to a printer selected based on the geographical location and positions of the network nodes. More generally, if in a network, a set of resources is shared among a set of n nodes, localization could significantly enforce equitable sharing of the set of resources. In addition, localization allows better enforcement of security policy, which is a set of rules and requirements defining how to protect and manage an information system to achieve some specific security objectives. The whole idea is to appropriately place control of the resources. For instance, a user, can be prohibited access to sensitive files from a given building when he or she is located in a special area. Other users may not be allowed to carry laptop computers outside the company's building. This can be achieved by having an application manage the location of all laptops (Obaidat and Boudriga 2007).

Another use for localization is in the routing process, where a node location can be used as a routing criterion. In the context of wireless mesh networks, a node sends a message (to be routed to a destination) to the node closest to the destination, among those nodes that provide the highest data throughput or the minimal failing rate in order to guarantee efficient message delivery. In addition, location-aware services can be accessed, offered, and managed based on location-based information. For example, in a replicated multimedia service, the server can be

selected (or reselected when the user moves) based on the user location. Another example is seen in the emergence of location-based services. Recently, the need for wireless localization became concretely materialized as a safety requirement for cellular mobile callers. For instance, the wireless enhanced 911 requirements (E911), mandated by the U.S. Federal Communication Commission (FCC), seek to improve the effectiveness and reliability of wireless 911 service by providing additional information on wireless 911 calls.

The wireless E911 program is divided into two parts called Phase I and Phase II. Phase I requires carriers, upon valid request by a local Public Safety Answering Point (PSAP), to report the telephone number of a wireless 911 caller as well as the location of the antenna that received the call. Phase II requires wireless carriers to provide more precise location information, including the caller location (within 50 to 300 meters in most cases). Such requirements have motivated the development of novel location-sensing positioning techniques for an accurate estimation of caller's location in indoor and outdoor surroundings.

Nowadays, the widespread use of wireless networking technology including Wi-Fi, Bluetooth, and cellular phone networks, has led to the need to have wireless devices be available through indoor and outdoor environments. Because these devices are equipped with radio frequency components that can be used to sense location, and because these devices represent a computing platform able to run location-based applications, localization services in wireless networks are going to become a part of everyday life. Localization will not be imposed only for emergency and safety purposes. On the contrary, localization will be driven by commercial services and applications able to exploit such valuable information (i.e., the user's position) to enhance their scope. These applications range from fleet management and asset tracking to security access and mobile advertising. To further emphasize the need for wireless localization, we provide below some specific examples of future services and applications that can be enhanced by the use of location information:

1. Fleet management is currently the main domain covered by commercial wireless localization services for clients such as taxi services, shuttles, and emergency vehicles which are constrained to act efficiently in a timely manner. Locating vehicle position is of high importance for the management of the fleet and the efficiency of the service the fleet provides. In this context, the Global Positioning System (GPS) is widely used. It computes users' locations based on signal reception from at least four satellites in a network composed of 24 running geo-orbital GPS satellites.
2. Asset tracking has also demonstrated an important need for wireless location-based applications. Tracking covers a large spectrum of services that are required to cover large geographic areas, provide good estimates of the asset location, and guarantee the privacy of related information (such as location, asset identity, etc). Examples of tracking services include: a) vehicle localization; b) car protection against theft; and c) safety and emergency applications, including the location of individuals. Wireless localization may also serve for advertising purposes. For instance, an application can use mobile devices to advertise goods in the mobile area. The content of the advertisement may need to be changed from one area to another to attract users more successfully.
3. The proliferation of mobile cellular phones has encouraged people to carry mobile devices wherever they are walking, driving, or working. The availability of mobile devices, combined with localization techniques, will ameliorate daily life of citizens, because those devices may be transformed into real-time contextual information sources that can be used to monitor daily services such as road traffic, making it possible to avoid traffic jams or find the nearest point of access. In addition, wireless localization technology can be efficiently used to monitor users' interaction with their environment; and thus opening up new opportunities for location-aware applications. For example, profiling customers based on temporal location information can open the door for applications that can better cope with customer behavior and needs.
4. Currently, a great deal of interest in security is attracting research work in wireless communication. Location information may be used to enforce some security measures, such as filtering users' traffic based on their location, or controlling access to shared resources based on location-based security policies. The need and importance of wireless localization continue to attract many efforts to detect intrusion and anomalies in localization platforms and to protect communication related to location information.

LOCALIZATION ISSUES

Wireless networks (such as the GSM, UMTS, 802.11, and 802.16) differ in terms of technology, topology, and infrastructure. Each one of these networks provides different technical challenges to implementing a fast, accurate, and robust positioning system. Therefore, it is not feasible to choose one positioning system as a universal solution to enable roaming among these networks, (to locate users and use existing wireless devices including laptops, PDAs, and cell phones) without any need to install or acquire additional hardware or modify the existing infrastructure. A wide spectrum of works has provided interesting discussion about current localization technologies and applications, and has addressed technical challenges and limitations (see list of references).

A position may be referred to by using an *absolute* reference or *relative* reference. An absolute reference places an object (a mobile station, in general) within a common frame of reference. For example, the GPS navigation system gives an object's position in terms of latitude and longitude and possibly altitude. On the other hand, a relative reference is described on a local frame of reference relative to some particular object of interest (such as a base station in GSM). Localization aims to make available two varieties of information, a *physical location* and a *symbolic location*. A physical position is typically defined by a set of coordinates in either two or three dimensions that

identify a particular point, in space or on a surface such as a map or the plan of a building. A symbolic position is a more theoretical concept that is basically defined in relation to other objects or places. It may be said that a location is in a particular room, or under the coverage of a particular radio cell. Physical location is accurate in comparison with symbolic location because each position is unique.

In a localized computation system, the responsibility of computing a location is placed on the mobile terminal of the object being located. The Global Positioning System (GPS) system is an example of a localized computation system, in which a satellite system provides the reference from which positions can be calculated, but knows nothing about the location of a particular device. Alternatively, an infrastructure-based system assumes that the location is calculated by the system for its use or for transmission to a device. Localized computation may be required if privacy is an issue, while an infrastructure-based system may be appropriate to reduce power consumption and computational power required at the mobile device.

Four key features of location systems can be distinguished: *accuracy*, *precision*, *scale*, and *identity recognition*. While accuracy refers to the granularity of the measurement used to locate the object, precision is a measure of how often the system is expected to achieve a defined level of accuracy. These two features are strongly related and should be addressed together. A system may be described as reaching an accuracy of 1 meter with a precision of 95 percent, meaning that positions within 1 meter of the true position will be reported 95 percent of the time. On the other hand, scale refers to the range of a system and the number of mobile devices it can service. A system may provide locations within a room, throughout a building, across a city, or worldwide (as in the case of GPS). The number of clients a system can support may be limited by the computation power or the network bandwidth. It may be unlimited if mobile devices determine their own positions. Finally, identity recognition is the ability of a system to determine the identity of the mobile devices that it locates. Identity information may be useful in cases in which mobile clients require service implementing authentication.

The localization problem has received considerable attention in the past, because many applications need to have the location in which objects or individuals can be found. Therefore, various location services have been developed. No doubt, the GPS is the most well used location service in use today. The approach taken by GPS, however, is inappropriate for low-cost networks (such as ad-hoc networks and wireless sensor networks) because the GPS is based on an extensive infrastructure. Therefore, cost is an important requirement to consider for the deployment of any location system. Cost may be measured in terms of capital expenditure, time, and other factors such as bandwidth and network resource use. It is also necessary to be aware of the environmental *limitations* of the location system to be used. For example, GPS systems do not work effectively indoors.

There is always a trade-off between cost and location accuracy. In fact, providing a high degree of accuracy

typically requires expensive acquisition and installation of sensors, deploying dedicated infrastructure, and using sophisticated signal propagation models. For instance, Cambridge's Active Bat system (Addlesee et al. 2001), which can locate users with a maximal deviation of 9 centimeters of their true position, requires that each user to be identified wear a special badge. It also needs a large infrastructure of fixed sensors and requires accurate placement of sensors. On the other hand, the use of location methods such as the OTD (Observed Time Difference) (Sun et al. 2005) scheme, which is based on observing the time difference feature of existing GSM cellular network systems to locate users, represents an inexpensive solution. It does not require acquisition of any additional hardware or software on the existing handsets. However, it only provides accuracy between fifteen to a hundred meters.

Wireless cell networks represent promising candidates for location services. Nowadays, these networks are covering a large part of the world and allow phone service companies to provide the location of users based on the observation of phones by cell towers. However, the position accuracy provided is too weak (on the order of hundreds of meters), and heavily depends on the cell size, in addition to the wireless environment characteristics, channel fading, interference, and multipath conditions. While the Enhanced 911 requirements have driven providers to supply handsets with GPS, the accuracy did recently become very close to hundred of meters. While such a value may be sufficient for emergency purposes, it may be too inaccurate for many other localization-based indoor services. Although GPS was widely used in navigation, it cannot be considered an essential location solution due to many limitations related to signal weakness. Indeed, GPS reliability is lost when used in indoor environments or in highly dense areas.

Wireless IEEE 802.11 represents an interesting networking technology for providing accurate positioning systems. Based on this technology, several localization systems were proposed. For example, the RADAR system (Hightower and Borriello 2001) was developed by Microsoft to locate users in the proximity of base stations with an accuracy of 3 meters. However, such a system requires extensive calibration by taking readings on a 1 meter grid, and its enhancement to three-dimensional areas is difficult. In addition, RADAR suffers from the environment sensitivity issue. Actually, weather variation may alter signal strength, and thus degrades the localization process.

Positioning in sensor networks is of particular interest due to its challenging issues. Wireless sensor networks are used in many applications, including environmental and industrial ones. They are composed of mobile nodes equipped with sensing capabilities. Sensor nodes are typically deployed in high numbers, and are very often assumed to operate autonomously. Consequently, the final position of these nodes cannot be determined at deployment; that is why localization awareness is essential in sensor networks. A wireless positioning system for sensor networks should be designed with consideration of the fact that sensor nodes are constrained to be inexpensive, of small physical size, limited power, and reduced memory and computation capabilities. For instance,

equipping a sensor node with a GPS receiver is typically inappropriate because it increases the cost and energy consumption in sensor networks.

Security presents a critical issue for wireless localization. Unlike mobile-based location technology, network-based technology, such as cellular network or WLAN, does not involve the mobile station in the computation of its position, (Sayed, Tarighat, and Khajehnouri 2005). Position is usually computed by the network infrastructure, and is sent back to the mobile station. While in network-based technology, no modification is required to be implemented in the mobile node; users need to trust the provider, to be sure that the provider protects the information related to their position, and that transmission is done in a secure manner. In mobile-based location technology such as GPS, the mobile station listens to satellites and estimates its own position locally. Security of position information becomes a major issue only if the mobile device needs to send it to the network core.

A final interesting issue is related to position representation, which should take into consideration the set of constraints that are imposed by communication, interpretation, and storage of such information. Broadly speaking, no single representation is useful in all circumstances. Where in general cases sensors provide numerical coordinates in the form of (x, y, z) , some applications based on sensors require more semantic information, such as a building, floor, room, and desk; or more specific numerical detail such as probability or uncertainty. In other circumstances, such as fleet management, both coordinates and additional information are required, such as weather, terrain characteristics, and traffic pattern.

SIGNAL PROPAGATION AND LOCALIZATION

Phenomena such as signal attenuation, reflection, scattering, and diffraction have important roles in location estimation. Their effect is more significant in non-satellite systems that have to operate in complex propagation environments, such as urban or mountainous areas. This section gives the most important issues in radio propagation related to localization.

Principles

The power density flow, F , is given by $F = P_T G_T / 4\pi d^2$, where P_T is the transmitted power, G_T is a factor characterizing the transmitting antenna, and d is the distance. The received power P_R , which is given in decibels, can be shown to be equal to:

$$P_R = P_T + 10\log(G_T) + 10\log(G_R) + 20\log(\lambda) - 20\log(d) - 22 \quad (1)$$

where λ is the wavelength and G_R is the gain of the receiving antenna. This equation is valid in free-space environment, where there are no reflections, no absorption, no diffraction, and no distortions. If the line-of-sight between transmitter and receiver is obstructed, the received signal power P_R is significantly smaller than the

Figure 1: Propagation mechanisms (reflection (1), scattering (2), diffraction (3), and (4) line-of-sight)

value provided by Equation (1). Because the medium is mainly the atmosphere and, to a lesser degree, materials such as glass, concrete, and wood, the signal loses a certain proportion of its energy due to interactions with the medium on every unit of distance it propagates. In fact, absorption causes the power density flow to decrease proportionally to γ^{-d} , where γ is a parameter that depends on the medium and signal frequency. This means that the curve representing the loss in terms of distance s linear. Absorption loss is particularly great in the upper microwave band, where frequencies are higher than 10 GHz. Absorption caused by media other than air is basically high.

In addition to absorption, obstructions cause the wave to be reflected, which further decreases the amount of energy passing through the wave. Reflection occurs when a wave meets an obstacle with of a size larger than the used wavelength. The component of the wave reflected back usually loses part of its energy by absorption to the material; the remaining part passes through the reflecting object. The received signal consists of the line-of-sight ray and the reflected ray. The two rays arriving at a receiver can have different phases and, in the worst case, they can cancel each other out. The magnitude of the reflected signal depends on the properties of the reflecting surface, the frequency of the wave, and the angle of incidence (Figure 1).

On the other hand, when a wave passes an edge (such as a corner of a building), the wave curves around the edge and continues to propagate. This effect is called diffraction. The more the wave has to curve around a corner, the more it loses its energy. However, in practice the diffracted waves can be neglected if there is a line-of-sight between the transmitter and the receiver.

Finally, scattering is another source of energy loss. Scattering occurs when the propagation path contains obstacles whose dimensions are comparable to the wavelength of the incident wave. The radio wave is scattered in a number of directions. Scattering is the most difficult event to predict, compared to reflection and diffraction.

Propagation Models

Prediction of radio wave propagation is useful in location estimation. Propagation models are used to predict the

properties of the propagation waves, the received signal and its variability. They also can help predict many other parameters that affect communication systems. A propagation model can be defined by a set of mathematical expressions, diagrams, and algorithms to represent the radio characteristics of an environment. Various levels of abstraction can be used for construction of the propagation models, depending on the amount of available information about the environment and the required accuracy of the predictions. For example, in planning a satellite communication system, sufficient accuracy is generally reached by taking into consideration free-space attenuation, absorption, and ground reflection. In addition, in urban areas, reflections and diffractions caused by buildings and scattering caused by trees have a strong influence on wave propagation. Based on this, propagation models can be divided into three categories: general models, geographic models, and empirical models.

General models typically describe the received power as a function of the distance between the transmitter and the receiver. One of the most interesting general models one can consider is the *log-loss model*, which is an extension of the free-space attenuation of Equation (1). The received power is given by:

$$P_R = P_T + a + bx \log(d) + c \quad (2)$$

where a and b are parameters indicating how the signal strength decreases as a function of the distance, and c is an error term. If the value of b is -20 , the attenuation corresponds to the free space model. If geographic information such as earth topography and land use maps are available, geographical models can be used to predict propagation. Such models can be established before a location system is implemented. The so-called ray-optical models use reflection and diffraction equations to model the paths of signal using two approaches: ray launching and ray tracing. In the first approach, several rays are sent in all directions from the transmitter. The rays proceed straight on until they hit an obstacle, creating one or several reflected or diffracted rays. A prediction of the resulting field is estimated by considering at each point all the rays that have passed through that point. In the second approach, one can start from some point in the prediction area, and considers potential rays arriving to that point from all directions. Figure 2 depicts ray launching (a) and ray tracing (b).

Empirical models use data collected in the same location where the model is used. In contrast to the aforementioned models, empirical models can be used only when the system is in operation. The data are used in a way similar to inference to obtain information on the parameters of the signal in different parts of the area. Empirical models are potentially accurate, because their predictions correspond to the actual propagation phenomena, even when no information is available about the environment. However, the major disadvantage of empirical models is the need to reconstruct them every time the environment changes.

Location Estimation Models

Location estimation is the act of obtaining the location of a mobile entity. Several location estimation techniques have been developed. A large set of applications of location estimation use the GPS satellite system, which provides location estimates with an accuracy of a couple of meters. They also use techniques that use signals between the mobile entity (to locate) and terrestrial transmitters, which can be dedicated for this purpose or be apart of a communication system (such as a cellular telephone system). Accurate estimates require measuring the strength, time delay, angle of arrival, or other properties of the signals transmitted between the mobile entity and the base stations. In the geometric approach to location estimation, the measurements are transformed into distance and angle estimates.

Several ways can be considered to distribute the estimation location between the mobile entity and the other components of the system. The observed signals can be sent or received by the mobile entity. The component performing the actual location estimation can be different from the component observing the signals. In mobile-based estimation, the mobile entity performs the necessary measurements of the downlink signals to deduce its own location without any uplink communication. For this to be achieved, the network has to broadcast some additional data, such as the locations of the base stations. Therefore, the approach is called the network-assisted technique. On the other hand, if the mobile entity performs the measurements and transmits the results to the network to be processed, the approach is called the mobile-assisted technique.

Location estimation can be performed using various measurements. When the approach is geometric, the

Figure 2: Ray-optical models

measurements are transformed into distances or angles with respect to a set of reference points (base stations, for example). In the angle-arrival location estimation method, the direction of the signal arriving from the mobile system to two base stations is measured. If the locations of the base stations are known, one can use triangulation to deduce the location of the mobile system. Angle measurements require additional hardware to be installed, such as antenna arrays.

If the time delay between transmission and reception of the signal is known, one can estimate the distance by multiplying the time delay by the speed of the light. Various distance estimates can be used to estimate location with the time of arrival method. However, it is clear that even a small error in the clock at the transmitter or the receiver can generate a major error in distance estimation. One way to alleviate the synchronization problem is to use differences in the delays of several base stations instead of absolute times. Time differences are used in the time difference of arrival method, which computes the difference in time delays, $r_{i,j}$, between the mobile system and base stations i and j using the following equation:

$$r_{i,j} = \sqrt{(x_i - x)^2 + (y_i - y)^2} - \sqrt{(x_j - x)^2 + (y_j - y)^2}$$

where (x_i, y_i) , (x_j, y_j) , and (x, y) represent the coordinates of base station i , base station j , and the mobile station, respectively.

Finally if the signal strength is known, the distance can be estimated in a way similar to the one used in the time of arrival method. Unfortunately, it has been noticed that signal strength is not sufficient for an accurate location estimation.

BASIC LOCATION TECHNIQUES

This section divides location techniques into three classes: a) triangulation-based, which exploit the geometric properties of a triangle to compute location; b) proximity-based, which determine whether or not the object is near a known location; and c) fingerprinting-based, which estimates the observer location or mobile position based on the signature of sensor data. For each class, the section describes the basic concept of the used techniques and provides an example of a localization system.

Triangulation

Triangulation is the method that exploits the geometric properties of triangles. It computes the node position using measured distances from at least three non-collinear points in a two-dimensional plane, and at least four non-collinear points in a three-dimensional plane. The measured distance basically be obtained using three possible methods: direct measure, time of flight (ToF), and signal attenuation. Direct measure is a method that lets the mobile entity automatically coordinate its physical movements (Hightower and Borriello 2001). The method is very complicated to implement, despite the simplicity of the underlying concept. The mathematical notions relative to techniques described hereinafter are written based

on Sayed, Tarighat, and Khajehnouri (2005). These notions include: the time of arrival (ToA), the time difference of arrival (TDoA), and the Angle of Arrival (AoA).

ToA: The ToA method is based on computing the time that a signal takes to move from a mobile node to a reference point. Suppose, for instance, that a wireless signal pulse emitted by a mobile entity takes 10 microseconds to reach a receptor at a point P . As the signal has a velocity equal to the speed of light, the distance is for about 3 kilometers around the central point P with respect to $(n-1)$ fixed points denoted by $(x_2, y_2), \dots, (x_n, y_n)$. We now explain how to estimate the node position in a Cartesian coordinate system. We denote by (x_m, y_m) the coordinates of the mobile in such two dimensional system. The coordinates can be computed by solving the following equations:

$$d_1 = x_m^2 + y_m^2 \text{ and } d_s = (x_s - x_m)^2 + (y_s - y_m)^2, \quad \text{for } 2 \leq s \leq n \quad (3)$$

where the unknown position is denoted by (x_m, y_m) and (x_s, y_s) , which denotes the coordinate of a given fixed point s . The system can be linearized by subtracting the last equation from the first $(n-1)$ equations. Reordering the terms gives a proper system of linear equations. This called multilateration.

Figure 3 depicts such a situation where n is equal to three distances, d_1 , d_2 , and d_3 , that separate the mobile node from the three points BS1, BS2, and BS3, respectively. It can be seen that the two solutions (x_m, y_m) can be obtained by solving the first two equations. The third equation will help resolve ambiguity by choosing the solution that results in the shortest distance. To improve this, measurements need to be able to efficiently combine more than three sources, mitigating potential errors (mainly due to noise and inaccuracy) that could affect the set of measurements d_i . To provide a solution to this issue, techniques such as the maximum likelihood estimator MLE, (McGuire, Plataniotis, and Venetsanopoulos 2003) or the least square solution (Sayed, Tarighat, and Khajehnouri 2005) can be used.

TDoA: One important issue that related to the use of the ToF technique is synchronization between the sender and receiver so that d_i is the actual distance. In this context, the higher the velocity of the signal, the higher the

Figure 3: Time of arrival localization technique

resolution of the sender and receiver clocks should be. For instance, using light pulses requires a clock, which is of six times the magnitude of the one used with a sound wave (314 meters per second). To avoid generating errors in the location estimation using the ToA technique, the TDoA is introduced. A difference between time of arrival of the mobile signal at point P_i and P_1 is defined by $(t_i - t_1)$. Consequently the related distance difference can be written by the following relation:

$$d_{i1} = d_i - d_1 = (t_i - t^0)c - (t_1 - t^0)c = (t_i - t_1)c$$

Now, it can be seen that such a difference is independent of the mobile clock time. The set of the aforementioned equations can be rewritten under the form:

$$-x_i x_m - y_i y_m = d_{i1} d_1 + \frac{1}{2}(d_{i1}^2 - K_i^2), \text{ for } 1 < i < n. \quad (4)$$

The obtained equations can be rewritten in a matrix form as follows:

$$H_x = d_1 c = e \quad (5)$$

where:

$$H = \begin{bmatrix} x_2 & y_2 \\ x_3 & y_3 \\ \dots & \dots \\ x_n & y_n \end{bmatrix}, \quad c = \begin{bmatrix} -d_{21} \\ -d_{31} \\ \dots \\ -d_{n1} \end{bmatrix}, \quad e = \frac{1}{2} \begin{bmatrix} K_2^2 - d_{21}^2 \\ K_3^2 - d_{31}^2 \\ \dots \\ K_n^2 - d_{n1}^2 \end{bmatrix}$$

This can be easily solved.

AoA: The AoA localization method is based on measuring the angle of the incoming signal from at least two fixed points, and estimating the mobile position using triangulation. To do so, directional antenna arrays should be used, and the angle of arrival can be computed by measuring the phase difference or the power spectral density between or across the antennas array. Briefly speaking, let us consider n fixed points $P_i = (x_i, y_i)$. For every, P_i , let i denotes the angle of arrival of the incoming signal from the mobile M whose coordinates are (x_m, y_m) . The latter can be described under the relation:

$$\begin{bmatrix} x_m \\ y_m \end{bmatrix} = \begin{bmatrix} x_i \\ y_i \end{bmatrix} + \begin{bmatrix} r_i \cos \alpha_i \\ r_i \sin \alpha_i \end{bmatrix}$$

More generally, we have: $Hx = b$ with:

$$H = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 1 & 0 \\ 0 & 1 \\ \vdots & \vdots \\ 1 & 0 \\ 0 & 1 \end{bmatrix}, \quad x = \begin{bmatrix} x_m \\ y_m \end{bmatrix}, \quad b = \begin{bmatrix} d_1 \cos \alpha_1 \\ d_1 \sin \alpha_1 \\ x_2 + d_2 \cos \alpha_2 \\ y_2 + d_2 \sin \alpha_2 \\ \vdots \\ x_n + d_n \cos \alpha_n \\ y_n + d_n \sin \alpha_n \end{bmatrix}$$

which yields the least square solution of x .

The last method presents several advantages when compared to ToA and TDoA. These include the following; a) the number of fixed point are less than those of ToAs and TDoAs; and b) no synchronization of the fixed points clocks is required. However, because AoA requires the use of directional antennas, the angle of arrival is very difficult to compute at the phone level for 2G networks unless an overlay of AoA sensors is appended to the infrastructure, which makes the solution expensive. On the other hand, the AoA localization technique is not well suited to the urban environment, because the accuracy of the estimated position is subject to degradation due to multipath propagation and reflection (see Figure 4).

Signal Strength

In cellular networks, base stations are constantly transmitting signal on the control channels while a mobile listens on the air interface and making measurements for handover decision. These measurements, which contain the signal strength from the serving and the neighboring base stations, can be used to compute the distance that separates the mobile from the base stations. Using signals from at least three different base stations, a triangulation can be performed to compute the location of the mobile station. In the case where location computation is executed at the mobile level, the base station should send its coordinates. If the computation is to be performed at the network level, modifications need to be introduced to the mobile in order to enable it sending these measurements in idle mode.

On the other hand, in reality propagation conditions are far from free-space propagation and the use of such a technique faces many challenges. In fact, in urban areas, signal degradations due to multipath fading and shadowing are very important. Moreover, the signal level decreases more rapidly than in rural areas. Thus, an efficient environment-dependent propagation model needs to be considered to estimate the mobile position based on the received signal strength.

Because the transmitted signal power at the base station, the received signal power at the mobile station, and the antenna gain are known to the system, the pathloss can be computed as:

$$\text{Pathloss} = \text{Power at MS} - \text{Power at BS} \\ - \text{BS Antenna Gain} - \text{MS Antenna Gain}$$

Figure 4: Angle of arrival localization technique

Several mathematical models have been proposed that enable estimation of the mobile position based on the signal pathloss. The Hata-Okumura mathematical model (Hata 1980), which is solely dependent on the mobile position, can be used for location estimation. The Hata-Okumura model consists of the free-space loss and a correlation between the distance and the frequency of the signal. Okumura presented the functions graphically as curves. Different curves exist for open, urban and sub-urban areas.

Fingerprinting

One approach to overcoming the problem of signal irregularity is to let the system learn the signal characteristics. Theoretically, any signal information that depends on the environment in the neighborhood of the mobile can be collected and used to estimate the location of the mobile. This information may include the received signal strength, the multipath pattern of the transmitted signal, TDOA and AOA measurements, signal time delay, and channel impulse response. This information can be measured at different known locations and recorded. When a new point needs to be localized, these quantities can be compared to the ones encountered before. The new location can then be assumed to be close to the previously collected points that have similar signal characteristics. This technique is called *fingerprinting* and the collected characteristics are called *fingerprints*. Thus, to localize a mobile node using fingerprinting, the collected fingerprint has to be compared to the fingerprints collected during a training period, whose positions are known.

Fingerprint-based localization takes advantage of two factors: a) characteristics of signals collected by mobile terminals show considerable spatial variability, because a radio source may be observed differently from two positions a few meters apart; and b) the signal characteristics are consistent in time, because a signal at a given location is likely to be the same at similar moments. In addition, fingerprinting-based localization systems present the advantage of allowing very accurate estimation of the location. Such a localization technique can be used with various technologies and different types of signal characteristics. However, the system is highly reliable in the face of changes in the environment, such as construction of new buildings, weather conditions, and mobility of objects (e.g., cars and persons) in the environment.

Informally speaking, a fingerprinting-based technique operates as a 2-phase process. In the first phase (called the *training phase*), fingerprints are computed at a set of *Reference Points* (RPs) that are appropriately distributed over the coverage area. After visiting all the RPs, a database of location fingerprints is built. The fingerprints can be recomputed several times to cope with the time variation and the degradation that occurs in signal propagation for several reasons, including shadowing. The fingerprints also may need some processing before they are stored (e.g., averaging all the taken measures). Theoretically, one can consider that the more RPs are considered in the training phase, the better the position accuracy will be. However, if the RF number is too high, the training phase may become laborious.

In the second phase (called the *positioning phase*), the available signal fingerprint is retrieved at the mobile position. Then, it is computed, and the mobile location is estimated by comparing the latter with the RP's fingerprints that are stored in the database, using different possible searching/matching algorithms, which are classified as deterministic and probabilistic (Li et al. 2005). In the deterministic approach, an algorithm (e.g., nearest neighbor) can be used to calculate the distance between the measured signal parameters vector and the vectors in the database. The mobile position will be associated with the RP that represents the shortest distance. In the probabilistic approach (Kaemarungsi 2005), a model of signal propagation using a probability distribution may be required. Once the signal parameter distribution is detected at a given position, the conditional probability theory is used to determine the probability of the mobile location.

The fingerprinting approach can be used with different wireless technologies such as GSM and WLAN. It also works with different types of input data, but the most common fingerprints are signal strength and time of arrival.

CELLULAR/WIRELESS/AD-HOC NETWORK LOCALIZATION

The aim of this section is to provide an overview of the localization techniques and solution designs in cellular, wireless, and ad-hoc networks. For each one of these networks, we address frequently used technologies.

Localization in Cellular Networks

This subsection gives an idea of the set of solutions provided in the literature and the positioning algorithms used in 2G, 2.5G, and 3G cellular networks. Finally, this section briefly discusses some standardization issues.

Localization in GSM

Introduced in the early 1990s, the Global System for Mobile Communication (GSM) is today one of the leading digital cellular systems. The architecture of this network is hierarchical and consists of cells. A cell is of variable size. It represents the smallest unit which is covered by the radio signal and frequency of a single transmitter. As radio frequencies are limited, the cellular concept allows using the same frequency within cells away from each other. A GSM network can be seen as the union of a set of Base Station Systems (BSS) and a set of Switching Systems (SS). While a BSS is responsible for the radio tasks, the SS processes calls and performs subscriber-related functions.

Cell-ID. To set a call within a GSM network, it is necessary to know in which cells the communicating users are located. The identification of a cell is made by a *Cell Global Identity* (CGI). A CGI is structured into four parts: country code, network code, location area, and cell identity. The identity of the cell is located within two components. The first component is the *Home Location Register* (HLR),

which is a database that permanently stores and manages the operator subscribers. For every subscribed mobile, it includes the last serving cell location. The second place is the *Visitor Location Register* (VLR), which holds, for every local and roaming subscriber, some information including the Cell-ID. Because cells represent a fixed infrastructure, their identity can be translated to into coordinates and used for localization.

Such a technique is inexpensive and requires easy calculations to determine the position of the mobile. Moreover, it only requires minimal changes to the existing network infrastructure. In fact, a dedicated control channel needs to be used in order to transmit cell coordinates. However, this technique has a major drawback: level of accuracy. The accuracy is a function of the cell size, which varies from 1 to 3 km in urban areas and from 2 to 20 km in suburban and rural areas.

The Cell-ID positioning method was also proposed by the 3rd Generation Partnership Project (3GPP). Different from 2G cellular networks, a 3G mobile phone may perform a soft handover. In this case, it may be associated with different cell IDs; that is why all the returned cell IDs need to be combined in order to determine the proper Cell-ID.

E-OTD. The Enhanced Observed Time Difference (E-OTD) is a TDoA positioning method based on an already existing feature in the GSM system, the Observed Time Difference (OTD). The theoretical principle of the method is based on taking three measures: 1) the Observed Time Difference (OTD); 2) the Real Time Difference (RTD); and 3) the Geometric Time Difference (GTD). The first measure represents the time difference between the reception of bursts from two different Base Transceiver Stations (BTS). It requires the mobile to use technically advanced signal processing algorithms to discover the earliest arriving signal, rejecting multipath, for instance. The second measure is the synchronization interval in the network between two BTSs. It is equal to the time difference between the two moments at which the two BTS send the same burst. Because the network is not synchronized, the RTD is typically different from zero. Unlike OTD, RTD requires installing an additional component, called the Location Measurement Unit (LMU), in the infrastructure. Note that the LMU can be also installed at the BTS level. The third measure is the actual time interval between the reception of two bursts from two BTSs due to geometry. The measures discussed are related by: $GTD = OTD - RTD$. The GTD value defines a constant as a time difference between two BTS, and thus it produces a hyperbola. Because the mobile position can be estimated as the intersection of two hyperbolas, at least three BTS are required in The E-OTD method.

The advantage of the E-OTD lies in its accuracy. However, weak signal, multipath fading, and interference phenomena highly degrade the produced results. The drawbacks are obvious. Both network and mobile handset modifications are required, and a slow response time results.

Localization in 3G Cellular Networks

For the sake of simplicity and clarity, we discuss here a special case of 3G networks, the UTRAN (3GPP 2005)

(UMTS Terrestrial Radio Access Networks). In UTRAN, the Base Station is referred to as *Node B*, while the mobile terminal is denoted by *User Equipment* (UE). Two methods are used in 3G networks: the *Observed Time Difference of Arrival* and the *hybrid positioning* methods.

OTDoA. The Observed Time Difference of Arrival (OTDoA) method is considered as the E-OTD version in 3G cellular networks (Zhao 2002). The mobile position is computed based on TDoA technique and at least three fixed neighbors (Nodes B) are required. Inheriting the same weaknesses of the E-OTD in 2G cellular networks, the method's accuracy depends on the geographic position of the base stations, is subject to degradation due to multipath radio propagation, and is dependent on the precision of the timing measurements.

In addition to weaknesses common to the E-OTD method, in WCDMA networks where the same the frequency is used by all the base stations, in-band interference may affect the accuracy of the location estimation. In fact, when a mobile is near its serving site, reception of the signal of other base stations using the same frequency may be blocked. This is a bit problematic because at least three measurements from three different base stations are required. To mitigate the problem, another variant of OTDoA, called OTDoA-IPDL, was proposed. It makes every base station pseudo-randomly cease to transmit for an idle period on the downlink, during which time the mobile can measure other neighbor signals. In the case in which the transmitters are not synchronized, the Relative Time Difference (RTD) must be provided.

Hybrid Positioning Methods. To increase the accuracy, reliability, and coverage of the estimated positions, several hybrid-positioning methods have been proposed. Cell-ID, for instance, can be combined with the Timing Advance (TA) method, or the Round-Trip Time (RTT) for a hybrid positioning in GSM and UMTS networks, respectively (Borkowski, Niemelä, and Lempiäinen 2005). In rural and sub-rural areas where a line of sight may be available between the mobile and the base station, an AOA-RTT hybrid position technique has been provided as an UMTS location technique. A single Node B that is equipped with an array antenna may be enough to estimate the mobile location. The RTT resolution, the beam width of the antenna array, and the increase of location error with the growth of the distance separating the mobile and the base station, represent the potential limitations of this technique.

To increase the accuracy of hybrid positioning methods such as EOTD/AGPS, Cell-ID/AGPS have been proposed. OTDoA-AoA is another hybrid positioning technique provided for the 3G UMTS cellular networks. In fact, as in these networks, where the AOA and the OTDoA measurements will be available without additional costs, combination of these two techniques will be useful for enhancing accuracy of the estimated position. The accuracy thus obtained is better than that obtained when either of these two methods is used alone (Thomas, Cruickshank, and Laurenson 2001). The errors in AoA measurements (due to the lack of availability of a line-of-sight condition) will be correlated with the errors

in OTDoA measurements (due to timing measurement errors involving the serving base stations). The position estimation becomes possible using only two base stations simultaneously in the presence of a Non-Line of Sight Problem (NLoS).

Localization in Wireless LAN

Recently, great emphasis has been placed on development of WLAN-based indoor positioning systems, including Bluetooth and WiFi. The decrease in cost of WLAN networks made them interesting for use as positioning systems. Two main approaches have been proposed in the literature for WLAN indoor positioning solutions: client-based systems and client-assisted systems. The first approach assumes that a client performs location estimation based on scene analysis or signal strength characteristics. With the latter, no supplementary hardware is needed because signal strength characteristics are part of the operating mode of the wireless hardware.

Two major localization solutions are based on signal strength: the propagation model and the empirical model. The propagation model is based on the fact that as a signal crosses an environment, it loses its strength, depending on the distance and the properties of the environment. Using a theoretical model to describe distance in terms of signal strength parameters, the node location can be computed. The use of such a method provides accuracy that is somehow proportional to the complexity of the model used. The localization is fairly accurate when the mobile is in the proximity of the access point, and decreases as the distance between the mobile and the access point increases.

The empirical model is based on the use of pre-recorded information on signal strength for a set of locations. It operates in offline and online phases. In the offline phase, an RF map is created. In that case, a number of points are selected and traversed, and the received signal strength from all audible access points' measurements are collected and stored in a database. Later, in the online phase, when a mobile entity wants to estimate its location, signal strength from all the access points is assessed and the database is queried for the closest match. The match obtained will be considered the location.

One drawback of such a solution is the effort to be spent in the offline phase. In fact, the radio wave properties may vary depending on the number of people in the monitored area, the temperature and the humidity. Moreover, because the solution is based on the variation of the signal strength, which becomes unnoticeable below some variation, by which the location accuracy is bounded. Nonetheless, despite these drawbacks, the empirical model is more accurate than the propagation model.

Localization in Ad-Hoc Networks

Ad-hoc networks represent a growing area in wireless networks. They represent a group of nodes linked via a wireless medium. A particular and important example of ad-hoc networks is the ad-hoc sensor network, whose nodes are expected to perform distributed sensing.

Sensor ad-hoc networks have been widely used in many attractive applications including intrusion detection, health care, and wildlife monitoring. They are designed with constraints related to low cost, moderate use of computational and memory resources, and power limitation.

Types of Localization Solutions. Localization solutions in ad-hoc networks can be classified into three categories: localization with beacons, localization with moving beacons, and beacon-free localization. The first category of localization solutions in ad-hoc networks assumes that a fraction of nodes, called *beacons* or *anchors nodes*, have a priori knowledge of their positions. Nodes with an unknown initial position are called *unknowns*. To define their location, the nodes start by estimating their 2D position using a proximity-based model (at least three beacons are available in its coverage) or ranging-based methods (e.g., RF time of flight, ultrasound, ultra wide band). After that, they refine their location to get better accuracy. Once a node has estimated its position, it becomes a beacon node and helps the remaining unknowns to estimate their positions.

Because the number of initial beacons is quite a few compared to the number of unknowns, it becomes possible to equip them with more power, sophisticated antennas, and even different hardware (e.g., hardware that uses GPS). It is even possible to use a node for the purpose of broadcasting location information (e.g., GPS satellites). The number and position of beacons have considerable influence on the accuracy of the location. For instance, in the case in which an environment is not homogenous, meaning that the computed location error may be different from one point to another, placing beacons in areas that provide the higher levels of error would be practical. Because energy consumption represents a hard constraint in sensor networks, the localization algorithms should be robust, and should use the minimum number of beacons possible.

The second category of localization solutions in ad-hoc networks uses a set of moving nodes that know their positions, called *anchors*, to achieve considerable savings in power consumption and cost. In fact, because the motion of the remaining nodes can be predictable, ad-hoc nodes can stay in sleep mode, and wake up only when the observers arrive in order to send data. Here, the data transfer can be initiated by the observer, which saves energy consumption. Because an observer needs a period of time t to send its data, an ad-hoc node should remain in the range of that observer during that period. Besides, it is important for the ad-hoc node to know whether it will remain within the transmission range for a sufficient amount of time, before it starts transmission. In the case where the ad-hoc node moves out of transmission range, it causes a data loss called outage. Because nodes are randomly distributed, it happens that an observer simultaneously receives different requests from ad-hoc nodes that should be sent in a limited time before they move out of transmission range. Thus, to avoid outage, it becomes crucial to use robust queuing systems that take into consideration waiting times and arrival processes.

The third category of localization solutions in ad-hoc networks operates without the use of beacons.

Motivations to design such systems are as follows: First, the use of beacons considerably increases the cost of building ad-hoc networks, especially in sensor networks. Second, depending on the environment and the ad-hoc node capability, it may not be feasible to set beacons and equip them with a localization system. (A GPS receiver, for instance, does not work in an indoor environment.) Third, even with the use of beacons, there might be some areas within the network that remain without beacons. Finally, because unknowns can act as beacons after their position is estimated, error may increase from one estimation to another. In a beacon-free localization, the position of every node is determined via node-to-node communication. At the beginning, every node starts with an unknown position. Then, they cooperate with each other to estimate their local distance. The estimated distance has a translation and orientation degrees of freedom. Simply put, the computed location is a relative position of the nodes compared to each other. In the case where an absolute position is required, conversion of the assigned orientation and coordinates should be done based on reference information (e.g., GPS).

Types of positioning algorithms: A wide spectrum of issues appears when designing positioning algorithms for Ad-hoc networks. This sub-section discusses the various possibilities related to existing positioning algorithms, including incremental versus concurrent algorithms, range-based versus range-free algorithms, centralized versus distributed algorithms, and multi-hop versus single-hop algorithms. Incremental algorithms start with a minimum number of nodes that know their position. Then, the remaining nodes recursively calculate their positions, using the relative distance separating them from nodes with known positions. Important drawbacks of this approach include: a) propagation error and cascading error may affect the accuracy of the whole positioning system; b) the nodes are vulnerable to failure, and c) the algorithms may not converge. Note that some algorithms may be applied to reduce propagation errors. On the opposite side, concurrent algorithms allow each node to calculate and refine its position in parallel with others. Thanks to the use of an iterative optimization scheme, differences between real and estimated positions can be reduced, and convergence of computation can be faster.

Range-based algorithms assume that some ad-hoc nodes can perform range-estimates by exploiting techniques such as ToA, RSSI, and AoA. However, the need for special hardware makes these nodes less portable and less cost effective. In addition, handling propagation issues—including errors, fading, and interference—is essential. In contrast, range-free algorithms assume that no node is equipped with special hardware for estimating its position. The location is estimated based only on the received message from neighbors. For instance, the APIT test algorithm (He et al. 2003) is used to determine whether a node is located inside or outside each triangle composed by all combinations of three possible beacons.

Centralized algorithms work by assuming that the ad-hoc nodes send estimates of their distance from their neighbors to a central node, which performs computations to determine the position of each node and

then broadcasts the results. These systems suffer from communication overhead and non-scalability of the network. Moreover, a failure of the centralized node leads to the disabling of the whole localization system. The use of centralized solutions would penalize nodes close to the server. The problem can become crucial when these nodes contain less memory and reduced bandwidth. Network partitioning is another challenge that makes centralization impossible. Finally, changing topology may disturb the centralized solution. In the opposite case, distributed algorithms assume that each node communicates with the others to independently compute its own location. Thus, scalability can be enhanced and communication overhead is reduced.

Multi-hop algorithms assume that a node does not directly receive signals from beacons. A node computes its location based on the number of hops that separate it from the beacon node and the average of the node density. DV-hop (Niculescu and Nath 2000) represents an example of a method that uses such an approach. Single-hop algorithms are similar to the positioning systems in cellular networks and WLANs, in which a node collects the TDoA, RSSI, or AoA information directly from the base stations or access points to compute location. However, when large or well-spaced obstacles occupy the monitored area, the DV-hop scheme will not provide accurate estimation of the node position because it does make assumptions about the internal topology of the deployment area. In this context, the node clustering approach was provided in Chan, Luk, and Perrig (2005), and is based on a clustering sensor network in order to create a regular structure of cluster heads (nodes selected as representatives to a small portion of the nodes in the whole network). The remaining nodes, which represent the majority of the network's nodes, will be able to use to cluster heads as reference nodes. The approach provided in Medidi et al. (2006) applies complex localization algorithms to estimate cluster heads' position using hop-based algorithm. After the cluster heads' coordinates are determined, the triangulation technique is used for mobile nodes' localization. Each node will calculate the Euclidian distance to the cluster heads in its neighboring clusters and then estimate the average hop distance using three-Euclidian distance and corresponding hop length. A location message is then broadcast to mobile nodes containing its coordinates and the estimated hop distance to x nodes (x will be chosen as a tradeoff between message overhead and accuracy of the estimated location). After receiving at least three location messages from different cluster heads, a node will be able to estimate its coordinates using triangulation techniques. The key power of the protocol lies in the possibility of using classical hardware without introducing any assumptions about the node's hardware.

Ecolocation (Yedavalli et al. 2005) is another recent approach which is dedicated specifically for wireless sensor networks. This approach is based the fact that the location of some nodes (called *reference* nodes) are known. Any one of the remaining nodes (called *unknowns*) which wants to compute its position broadcasts a localization packet. The technique does not convert signal strength values into distance estimates. The reference nodes will

collect some RSS measurements on that packet and send them to an entity responsible for estimating the location. The collected RSS measurements will be used to determine an ordered sequence of reference nodes. Because for every possible grid-point in the monitored area, the ideal distance-based ordering sequence of reference nodes is supposed to be determined from the outset, the two ordering sequences are compared. The best location estimate to the *unknown* node will be the one that maximizes the number of satisfied constraints, or the centroid of these locations in the case in which there is more than one location. Experimental results have shown that the echolocation technique provides better accuracy than that provided by Maximum Likelihood Estimator and Centroid localization techniques. Some other approaches such as the one reported in Ramadurai and Sichitiu (2003) consider the use of distributed localization algorithms using a probabilistic approach. They take into account range measurement inaccuracies. These approaches assume that nodes in a sensor network can belong to two different classes, namely beacons and unknowns. The key idea of such approaches lies in the fact that the probability distribution of each signal strength, as well as the mean and standard deviation, can be calculated and tabulated as a function of distance.

Localization in Wireless Sensor Networks (WSNs)

Because the main function expected from a WSN is event reporting, a significant and precise interpretation of such an event cannot be guaranteed unless its accurate location is determined. Localization in sensor networks is challenged by the limited capability of sensor nodes and the need for energy conservation. This is a conflicting-objective-based problem because: a) collaborative communication and computation among network sensor nodes becomes a requirement, b) communication among network sensor nodes should be minimized to reduce energy requirements; and c) power capability of sensor nodes is limited so that complex signal processing algorithms should not be used. To cope with these challenges, theories and models are needed to provide optimal coverage of the supervised area in preparation for tracking of target mobility (Hamdi, Boudriga, and Obaidat 2006).

The coverage approach is important in the sense that the optimal number of sensor nodes should be determined for a certain detection accuracy and quality, and the optimal positioning strategy of sensors should be determined. Many coverage optimality concepts were proposed in the literature, including: blanket coverage, barrier coverage, and sweep coverage (Hamdi, Boudriga, and Obaidat 2006). The first concept (blanket coverage) aims to maximize the rate of detection in the covered sensing area, while the second (barrier coverage) aims to minimize the probability of undetected penetration of nodes through the sensing area barrier. The last (sweep coverage) is a trade-off between the two quoted objectives, blanket coverage objective and barrier coverage objective). Developing an optimal node positioning strategy should be performed with awareness that other properties such as routing complexity and congestion rate

may be affected. In fact, because sensor nodes should forward gathered events to an analysis center, deploying a network with a high density will guarantee better coverage, but on the other hand, it may increase the likelihood of congestion. Four main deployment strategies were mentioned in the literature: *k*-coverage, (K, R_i) coverage, *k*-connectivity coverage, and *path observability*. In *k*-coverage (Kumar et al. 2004; Zhou, Das, and Gupta 2004), every point which is within the region A can be sensed by *K* sensors. Such a strategy allows reception of detection messages within the region even in the presence of packet loss, which is a very common phenomenon in multi-hop wireless sensor networks. In (K, R_i) coverage, *K* sensors are within a region A to track a target *t* having a radius R_i . In *k*-connectivity, the network is *k*-connected, meaning that there are *k*-nodes disjoint communication paths between every pair of nodes. Such a strategy is mainly used when the transmission and forwarding capability of the networks need to be enhanced. In *path observability* strategy, the focus is on exposure of the moving object to the sensing field, because the main objective behind the use of such a strategy is mobile target tracking in the monitored field. It becomes more important to address the problem of node placement strategy when the mobility or the dynamic activation of sensor nodes is taken into consideration. In fact, nodes may switch between “sleep” and “activate” for the purpose of energy control, and may also change their positions by time. In this context, more importance should be given by the literature on studying the impact of mobility and energy control on coverage.

To guarantee efficient use of the sensor network for tracking, node placement should be done in an optimal manner, covering the entire surveillance zone. In this context, the number of required sensor nodes is highly dependant on the localization technique that will be used to determine the node position. For instance, if the sensor network is modeled as a two- or a three-dimensional grid, the location of the target will be determined by pinpointing it at a grid point. With the granularity of a single grid point, it is generally difficult to locate a target using the location of one sensor. If sensors are positioned in such a way that a subset of them should cover every grid point, the precision of the trajectory of moving targets and their positions will be enhanced and easily determined.

To locate a target and track its path during mobility, several methodologies were proposed. While the traditional method could be based on the use of a centralized database or computing facility, the latter becomes a bottleneck in terms of requested resource and induced network traffic directed toward it. Therefore, such an approach is not adequate due to lack of scalability and absence of fault-tolerance. To avoid flooding, some approaches suggested not using all the nodes for tracking. Only a selection of nodes that have the best data collaboration can be used to save power and bandwidth cost. Several metrics can be used as the basis of selection, such as: a) detection quality (including detection resolution), sensitivity, and false alarms; b) track quality including tracking error and tracking length; c) scalability including network size, number of events, and number of active queries; d) solvability including fault tolerance; and e) resource usage in

terms of power/bandwidth consumption. With the use of such a concept, only the leader node will generate an estimate of the object state and will hand off the state information to the next selected leader. The latter could make a combination of the estimated information and derive a new state, and then select the next leader itself. The current leader will periodically return the information to the unexpected node via the shortest path. Some other distributed tracking schemes try to improve accuracy by combining information retrieved from several nodes instead of relying on one neighbor (Wang et al. 2003).

A SURVEY OF WELL-KNOWN LOCALIZATION SYSTEMS

This section describes three well-known, widely used, and accurate wireless localization systems. The first is one of the well-known Global Navigation Satellite Systems (GNSS) that was introduced by the United States and called GPS (Global Navigation Satellite) system, which represents the most familiar example of a location system and provides wide-area coverage. It is used extensively in military and commercial applications, such as vehicle tracking. The second system is the APS system, which was designed for localization in wireless ad-hoc networks. The third is the RADAR system, which provides localization in indoor environments based on the 802.11 wireless networking technology.

Global Positioning System

The Global Positioning System (GPS) is a worldwide localization system that covers almost the entire earth and provides real-time three-dimensional position (longitude, latitude, and altitude). The system was developed by the U.S. Department of Defense and was officially called NAVSTAR (Navigation Signal Timing And Ranging). The GPS system can be considered a combination of three main segments: the *space segment*, the *system controller segment*, and the *user segment*.

The Space Segment. This segment is composed of 29 orbiting satellites containing a minimum of 24 operating satellites. It is designed to maintain full operational capability even if two satellites are in failure state. The satellites are positioned in six earth-centered orbital planes; each one of them is inclined by 55 degrees with respect to the equator and is located at a distance of 12,000 nautical miles above the earth. Each GPS satellite takes 12 hours to orbit the earth and is primarily powered by sun-seeking solar panels while using Ni-Cad batteries as a secondary power. Every GPS satellite continually broadcasts its position and timing data via two UHF (Ultra High Frequency) radio bands, frequency designated as L1 and L2, respectively. The first frequency is designed for civilian use while the second is reserved only for military use. Two codes are broadcast on the L1 frequency: C/A code and P code. The C/A code, which stands for Coarse Acquisition, is available for civilian use and provides Standard Positioning Service achieving horizontal accuracy of 15 meters, approximately.

The second code, which stands for Precise Code, is broadcast on both L1 and L2 frequencies and is only available for military use.

Each transmitted signal is 1023 bits long and is transmitted using CDMA (Code Division Multiple Access) multiplexing method, which lets all the satellites share the same frequency. A GPS signal is composed of three different types of information. The first type is a *Pseudorandom code* that identifies which satellite is transmitting the information. The second type, which is called the *Ephemeris data*, is transmitted by every satellite to show orbital information relative to itself and to every other satellite in the system. It mentions where each satellite is located at any time. The third type, which is called the *Almanac data*, carries information about the status of the satellite and the current date and time.

The **control segment** is composed of a set of five monitor stations, three ground antennas, and a Master Control Station (MCS). The monitor stations track all satellites in view; accumulating ranging data. This information is processed at the MCS to determine satellite orbits and update each satellite's navigation message. Updated information is transmitted to each satellite via the ground antennas.

The user segment, which is composed of GPS receivers, uses the process of trilateration to estimate position, requiring that at least four satellites are within the line-of-sight of the receiver. Note that readers should be reminded that the satellite position is known by the receiver because it is transmitted as part of the message it sends. To measure its distance from every satellite, the receiver has to compute the time delay between satellite transmission and terminal reception and then multiply the time delay by the speed of light. As a GPS receiver is synchronized with a satellite, it generates the same pseudo-random sequence (the receiver is able to calculate the same identical sequence starting from a known seed number) at the same time. Upon receiving the sequence from the satellite, the receiver looks back in its memory to determine when the same sequence was emitted, and therefore infers the time delay. After computing its distance from four satellites, it computes its distance as the intersection of four imaginary spheres. Such a sphere is centered around a satellite and has a radius equal to the distance that separates the receiver from the satellite. In practice, the fourth measurement is required to correct the clock error.

Many sources of error may affect GPS measurements, including atmospheric effects, satellite orbit errors, receiver noise, multipath ambiguities, and satellite clock errors. As the GPS signal goes through the ionosphere and troposphere, it may be refracted and its speed can be changed unpredictably. This effect becomes more apparent when the satellite moves toward the horizon because the angle of inclination increases and the signal has to cross a thicker atmosphere layer. Depending on their frequencies, changes in speed are different from one signal to another. GPS receivers may exploit the received phase difference between L1 and L2 signals frequencies to infer the atmospheric effects and proceed with correction. Errors may also occur due to sunspot activity that creates interference with the GPS signal, measurement

noise, signal distortion caused by electrical interference, or even errors inherent in the GPS receiver itself.

Multipath reflections means that a signal is received by different paths, due mainly to reflection and refraction from the ground and surrounding terrestrial objects. Multipath reflections may also considerably affect position accuracy. For the case of long delay multipath signals, GPS receivers can proceed with filtering out using techniques such as Narrow Correlator Spacing (Cannon et al. 1994). As for short delay multipath, it may considerably reduce precision because the reflected signal can be very close to the real one. Special antenna features such as a ground plane, or a choke ring antenna can be used (Rao, Sarma, and Kumar 2006). Accuracy of the GPS positioning can also be affected by the *Geometric Dilution of Precision* (GDOP), which is a measure of the quality of the satellite configuration. This parameter value is computed from geometric relationships between the receiver position and the positions of the satellites that the receiver is using for navigation. A high GDOP value results when angles from receiver to satellites are similar, whereas a low GDOP value occurs when those angles are different. The higher the GDOP value, the lower the probability of precision.

To increase the accuracy of GPS receivers, several solutions have been proposed. Among these solutions, one can distinguish *Differential GPS* (DGPS), which uses a set of fixed ground based reference stations (also called GPS base station) with known location to reduce the effect of atmospheric errors during position computation (multipath errors are not resolved, however). Because its location is known, a GPS base station can compute errors (e.g., the timing errors) in its position calculation and broadcast this information to mobile GPS receivers in the same surrounding area. The receivers will correct their position estimation and reach an accuracy of 1 to 3 meters.

There are two modes of differential corrections: a) real-time differential GPS and b) post-processed differential correction. In the first mode, the location error is transmitted as a local signal and a mobile receiver directly provides the corrected position. However, this mode requires having a mobile GPS receiver equipped with correction software and able to interpret the base station signal. In the second mode, raw location values from mobile GPS receivers are combined together with data from base stations and a differential correction software is used to apply error correction. However, this solution requires that both mobile receivers and base stations be provided with storage capabilities. In the case in which the mobile GPS receiver and the base stations are produced by different manufacturers and experience compatibility problems, *Receiver Independent Exchange* (RINEX) format, for instance, may be used to guarantee compatibility (Cooksey 2006).

Several other techniques were proposed, similar to GPS (Wikipedia 2006). The major techniques include WAAS (Wide Area Augmentation System), EGNOS (Euro Geostationary Navigation Overlay Service), and MSAS (the Multi-Functional Satellite Augmentation System) which uses a series of ground reference stations to calculate location errors and then uploads such values to a

series of additional satellites. Additionally, an alternative to GPS was proposed by the European Union to be operational by 2010. The positioning system is called GALILEO and is intended to provide greater precision than that provided by GPS. The system will be composed of three orbital planes located at 23,222 km above the earth and inclined 56 degrees with respect to the equator. Each orbital plane will be composed of nine operational satellites and one active spare per orbital plane. The GALILEO system improves coverage notably in northern regions such as Scandinavia. The signal transmission is performed with more power in comparison with the GPS signal, and over wide frequency bands. This makes reception possible in indoor environments and improves robustness against multipath effects. GALILEO is not expected to replace GPS, but rather is expected to be combined with it for maximum coverage.

Four different navigation services will be provided by the GALILEO positioning system. The first, called Open Service (OS), will be available for free access and be broadcast in two bands at 1164–1214 MHz and at 1563–1591 MHz. In the case in which a receiver uses the two signals, it can achieve an accuracy of less than 4 meters horizontally and less than 8 meters vertically. The second provided service, called *Commercial Service* (CS), will offer accuracy of less than one meter for an additional fee. The system uses encryption to facilitate charging and introduces a third signal band (1260–1300 MHz) in addition to the two bands used in the OS service. The accuracy of location estimation may go down 10 centimeters if the system is used with ground stations. The third service is called *Safety of Life Service* (SoL). It provides accuracy comparable to OS service and is intended for safety-critical transport applications. The last service, called *Public Regulated Service* (PRS), is encrypted to control access and is available for security authorities.

RADAR

RADAR System is a Microsoft tool for user location and system tracking that uses ambient IEEE 802.11 signals to estimate position. This system's strong point is that it does not require any transformation or modification of the existing wireless infrastructure. RADAR assumes that a few access points (or base stations) are deployed in a manner that provides overlapping coverage. The basic version of the RADAR system allows computing of 2D positions of mobile devices, by taking measurements relative to Signal Strength and Signal to Noise Ratio at the base station when it receives a signal (Bahl and Padmanabhan 2000). However, providing localization in three dimensions such as in a multi-floored building remains a considerable challenge. Moreover, any mobile device to be tracked should support WLAN networking. Such a requirement becomes restrictive in the case in which devices are equipped with low computational and power capabilities.

To estimate the user's position, the system starts working in an offline phase by creating a radio map of the area under which it operates. This map represents a set of recorded information about the received radio signal from the access points as a function of the user's

locations in the building. An entry in the database is in the form of $(x, y, z; ss_i)$ where (x, y, z) represents the physical coordinates of the mobile where it takes the signal measurements and ss_i represents the signal strength that propagates from the access point number i . The basic version of the system uses three access points, in such a case; a database entry will take the form (x, y, ss_1, ss_2, ss_3) . Because the offline phase requires an important effort of deployment, two approaches were proposed for the creation of the radio map. The first approach is an empirical method that involves a mobile user that moves within the building and manually records its location and the associated received signal strength from access points that are within its range. The second method aims at creating a radio propagation model relative to indoor RF propagation in order to reduce dependence on empirical data. The model supports different building layouts, takes into consideration large-scale path loss, and attenuation due to obstacles (e.g., walls) between access points and receivers.

Later, in the online phase, the mobile takes a real-time measurement of the signal strength of each access point within its range and searches through the database for the entry producing the best match. The location associated with such an entry will be taken as the best matching location. To search through the database, the system uses a search technique called NNSS (or Nearest Neighbor(s) in Signal Space). The algorithm bases its search on computing the *Euclidian distance* (in the signal space) between the real-time computed set of measurements (ss_1, ss_2, ss_3) and each recorded set (ss'_1, ss'_2, ss'_3) in the radio map database. The estimated user location will be relative to the physical coordinates of the entry that minimizes the distance. Another variant of the algorithm proposes to take a particular interest when there are more than one matching entry in the database. In that case, the algorithm averages the physical location of closely matching entries and provides that average as the location estimation.

Two major drawbacks of the RADAR system can be mentioned: a) RADAR is dependent on changes in the environment such as weather, moved objects, and variation in hardware; b) RADAR does not scale over large areas mainly due to the necessity of extensive calibration. On the other hand, the system has shown good accuracy with the empirical model. In fact, the error distance, which is defined as the Euclidian distance between the real position and the estimated one, is shown to be lower than 3 meters, (this is typically comparable to the size of a room within a building). Additionally, the RADAR system was adopted in many commercial products including *Ekahau*, *Pinpoint*, and *WhereNet*, due to its effectiveness in terms of cost and accuracy. In comparison with other well-known systems, the RADAR location system provides less accuracy than indoor location systems (e.g., Cricket [Hightower and Borriello 2001]) but on the other hand, it does not require specialized infrastructure. Compared to GPS, RADAR provides better accuracy, but less coverage

The RADAR system has experienced several enhancements: a) the support of continuous user tracking, taking information from the past into account to better estimate the user's location; b) the use of an environment

profiling technique that takes into account changes in the environment conditions; and c) the extension of the NNSS algorithm to support three-dimensional environments (Bahl, Balachandran, and Padmanabhan 2000). This enables the RADAR system to use multiple radio maps dynamically and improves its accuracy.

APS

The Ad-hoc Positioning System (APS) is a range-free localization system. We demonstrate hereinafter how the APS system brings a solution to computation and power constraint challenges in ad-hoc networks and how it provides localization.

APS is a distributed hop-by-hop positioning algorithm that extends the Distance Vector routing (DV) and the GPS system. Starting with a set of nodes called landmarks (a concept inherited from GPS), which are highly powered nodes capable of performing self-location computation and which have good line-of-sight conditions. The APS system propagates position estimation capability to regular nodes using a hop-by-hop method (a concept inherited from DV routing). Note that the number of landmarks is supposed to be reduced and that regular nodes may not be in contact with enough landmarks. The key ideas behind the design of APS can be summarized by the following facts: a) distribution of positioning algorithms that face the challenges related to low memory and bandwidth, partitioning, and changing topology; b) minimization of node-to-node communication to preserve energy, c) tolerance to network disconnection; and d) absolute position providing in the GPS coordinate system. APS proposes a set of positioning schemes that depend on the node capabilities. The major schemes are the DV-hop, DV-distance, Euclidean, DV-coordinate, DV-bearing, and DV-position (Niculescu and Nath 2004).

DV-Hop. The Distance Vector-Hop (DV-Hop) scheme consists of three phases. In the first phase, nodes start using distance vector exchange to obtain the shortest path to landmarks in terms of hops. Every node will maintain a table $[X_i, Y_i, h_i]$ where X_i and Y_i represent the unknown coordinates of landmark i , and h_i is the number of hops that separate the current node from landmark i . The aim of the second phase is to let a landmark estimate the average size in meters for one hop and distribute it as a correction value c_i . In fact, given the distance (in hops) to other landmarks that it estimated in the first phase and the known coordinates of these landmarks, we can compute c_i as:

$$c_i = \frac{\sum \sqrt{(X_i - X_j)^2 + (Y_i - Y_j)^2}}{\sum h_i}, i \neq j, \text{ all landmarks } j$$

Such correction is distributed to the neighbors using a controlled flooding mechanism. In the third phase and after receiving the correction value, a node will be able to transform distances to landmarks in hops to distances in meters. The output will be used to perform trilateration and estimate the node's position in the entire network. The main advantage of the DV-hop method is characterized

by its independency to the range or angle measurement errors. However, it assumes that the network is isotropic (i.e., properties are the same in all directions) for a reasonable deployment.

DV-Distance. The DV-distance scheme introduces a little improvement in the distance-vector algorithm metric, compared to DV-hop scheme. In fact, the distance between nodes is measured using radio signal strength and is propagated in meters rather than in hops. Unfortunately, propagated errors in measurements weaken the method's accuracy.

Euclidean Propagation Model. This method is based on propagation of the estimated Euclidean distance to landmarks. As shown in Figure 5, the problem can be stated as follows: Given a landmark L and two nodes B and C that have already estimated their Euclidean distance (r_1 and r_2) to L , the aim is to help node A , which is in communication with B and C to estimate its distance d to L . The problem can be solved by considering the quadrilateral $ABCL$ because A already has estimated knowledge of the values of all the sides and one diagonal of the quadrilateral $ABCL$. Solving this problem yields to two possible values for the distance from node A to L . The *Neighbor vote method* can be applied to decide which value is acceptable, if there is a third node (D) that can be used. Replacing node C by D will lead to a pair of distance estimates. The correct distance is part of both pairs.

DV-Bearing. Given that the two neighbor nodes B and C know their bearings (the angle with respect to a fixed direction) to landmark L , a node A in the proximity of B and C can compute its bearing to B and C . After receiving their bearings from C and B , node A will be able to compute all the angles in the triangle ABC and BCL and therefore infer the bearing of A with respect to L . After computing its bearing with respect to three landmarks, node A can infer its position using the AoA technique.

DV-Coordinate Propagation Method: To use the method, a pre-processing phase is required. This phase aims at allowing every node in the network to establish its own coordinate system centered at itself. An assumption is made, stating that second hop information is available. As depicted by Figure 6, a node A , after estimating its range to node E and G and the range between them, chooses

Figure 6: DV-coordinate propagation

axes x_a and y_a as a local coordinate system. After that, it computes the coordinates of all immediate neighbors.

The second phase is registration with neighbors, which intends to let a node compute a transformation matrix with respect to its neighbors. Consequently, a node X , which receives from node Y the local coordinates of node Z , will be able to translate such coordinates to its own system. Later, at the DV propagation phase, only the coordinates of a landmark are forwarded from one node to another. When a node X receives the coordinates of a landmark, it immediately transforms them into its local system using the appropriate computed transformation matrix. To estimate its position, a node can choose between two methods that showed the same performance. In the first scheme, the node transforms all the received coordinates of landmarks and then solves the trilateration problem. In the second scheme, because the node has the coordinates of the landmarks in the global and local system, it computes a global transformation matrix and uses it to estimate its global coordinates.

One drawback of the method is error propagation. In fact, uncertainty in locally computed coordinates is amplified by the uncertainty that occurs due to application of the transformation matrix (uncertainty that comes from the registration phase) and then is propagated to neighbor nodes.

ADVANCED ISSUES IN LOCALIZATION

Several advanced issues related to localization in wireless networks are under investigation. The major issues include: a) indoor localization; b) the sensing of mobile resources and c) positioning security

Indoor Localization. Accurate indoor localization has been a constant objective of the wireless communication research community. Most research activities on indoor localization have been based on short-range signals such as 802.11, Bluetooth, and Infrared. However, a very few works have shown that indoor localization using wide-area cellular networks can reach high accuracy. Indoor cellular network-based localization has several advantages including:

Figure 5: Euclidean propagation model

1. A cellular network operates in a licensed band of frequencies, and thus does not suffer from interference from nearby devices.
2. A cellular network presents a stable environment that allows a localization system to operate properly for a long period before needing calibration.
3. The wide acceptance of cellular networks (e.g., GSM, UMTS) makes them appropriate channels for the delivery of localization-based value-added services.

Research in cellular network based localization would have to face several challenges including: a) achieving an accuracy that can compete with 802.11 localization solutions (by using diversity, for instance); and b) providing efficient localization in three-dimensional environments. The first accurate GSM-based localization solution has used the concept of fingerprinting to achieve an accuracy as low as 2.5 meters (Otason et al. 2005).

Mobile Sensing. The localization of individual mobile sensor nodes and mobile targets without relying on external infrastructure is receiving considerable attention because a wide spectrum of applications need to know the location of objects and individuals they are involved with. Recently, a number of localization systems have been proposed for wireless sensor networks (Langendoen and Reijers 2003). However, truly distributed localization algorithms should satisfy the following requirements:

- The localization algorithm should be self-organizing in the sense that it does not depend on global infrastructures. This implies that there is no fine control over placement of the sensor nodes when the network is deployed.
- It should be robust, meaning that it is tolerant to security intrusions and node failures. The nodes are also assumed to continue sensing even when they get out of coverage and report events when they return to radio coverage.
- It should be energy efficient in the sense that it requires little computation and communication, especially when security protection is required for the need of privacy and alert confidentiality.

The aforementioned requirements immediately eliminate almost all proposed localization for wireless sensor networks.

Secure Positioning. So far, the problem of positioning in wireless networks has been addressed basically in a non-adversarial environment. Nowadays, we observe two types of attacks on localization systems: internal and external. Typically, an attacker can perform timely attacks by delaying or speeding up the signal used for localization, or can perform power level modification attacks by replaying signals between nodes and base stations. Attacks are targeting all localization systems, propagation techniques, and estimation methods.

Examples of attacks have addressed the GPS system, because current GPS receivers can be completely fooled

by GPS satellite simulators that produce fake satellite radio signals that are stronger than the real signal. Civilian GPS devices were not designed for secure positioning. A few simple changes to GPS receivers would allow them to detect relatively unsophisticated attacks; but sophisticated attacks would remain very hard to detect. On the other hand, the techniques based on the received signal characteristics to compute the location can be misled by an internal attacker reporting a false power level to a trusted node or modifying the measured distance between two trusted nodes by jamming the communication between the two nodes or replaying their messages with higher power.

Several research works have addressed the secure positioning problem. In Brands and Chaum (1994), the authors propose an RF distance bounding technique that allows the nodes to “upper bound” their distances to other nodes and prevent internal attackers from reducing the measured distance. In Capkun and Hubeaux (2006), the authors analyzed the resistance of positioning techniques against position and distance spoofing attacks. They also proposed a mechanism, *called verifiable multilateration*, for secure positioning of wireless devices.

CONCLUSION

Recently, location-based services have gained considerable attention. Several kinds of services and applications need to be aware of their positions, including environment monitoring, target tracking, and intrusion detection. In this article, we stressed the need for localization in the wireless environment, and presented the various issues surrounding localization techniques. We also described the most important issues in radio propagation that are related to localization, particularly in non-satellite systems operating in complex environments. Moreover, several techniques for position calculation were described, and localization solutions for cellular, wireless, and ad-hoc networks were illustrated. For every one of these networks, a well-known, widely used, and accurate wireless localization system was described. This article has given special attention to advanced issues related to indoor localization, mobile resources sensing and positioning security.

The future outlook in wireless localization should address techniques for position estimation in ad-hoc and sensor networks in which the nodes’ computational resources are limited, infrastructure is absent, coverage problems may occur, environment is subject to intrusions, and a tradeoff between traffic overhead reduction and position accuracy is a concern. In general, indoor localization continues to require dedicated hardware and signal propagation schemes. Enhancing existing localization techniques used by cellular networks, for instance, to provide a global localization (for both indoor and outdoor) will be of high importance in terms of coverage, cost, and practicality. Finally and due to the increase and sophistication of security attacks, interest in digital investigation of security incidents continues to gain significant importance. In this context, providing new techniques of investigation that benefit from localization information will be of the utmost importance.

GLOSSARY

APS: Ad-hoc Positioning System. A positioning system that copes with the characteristics of ad-hoc networks (changing topology, low power constraints). It uses a distributed, hop-by-hop positioning algorithm that extends distance vector routing and GPS positioning. The algorithm assumes that only a small number of nodes are able to compute their absolute position themselves (called anchor nodes), and allows all the remaining nodes (called unknowns) to compute their positions based on their distance estimation to anchor nodes.

Bluetooth: A wireless personal area network technology, known as IEEE 802.15, which provides communication between digital devices, including PDAs, and mobile phones. The devices communicate when they are in range, using a radio communication system that induces low power consumption and requires unlicensed short-range radio frequency.

CDMA: Code Division Multiple Access. A technique that spreads a signal over a frequency band that is larger than the signal, allowing numerous signals to occupy a single transmission channel. Each signal is encoded using a pseudo-random sequence. Only the receiver, which knows the right code, can suitably decode the received signal.

Euclidian Distance: Represents the ordinary distance between two points. It is equal to the root square difference between coordinates of these points.

Free Space Loss: The loss of signal strength when ideal propagation condition are assumed: radio waves emanate from the source of radio energy and travel in all directions in a straight line (i.e., the effects of diffraction, reflection, and scattering are removed). The loss only depends on frequency and distance.

GPS: Global Positioning System. Represents the most known worldwide satellite navigation system. It consists of a network of 24 orbiting satellites that send radio signal, enabling GPS receivers to compute their three-dimensional position, velocity, and time.

GSM: Global System for Mobile Communications. Represents the most popular standard for cellular mobile phones in Europe. GSM is a second generation mobile phone system which operates in 450 MHz, 900 MHz, 1800 MHz, or 1900 MHz frequency band (some countries, such as the USA, use the 850 MHz and 1900 MHz bands because the 900 and 1800 MHz frequency bands were already allocated) and use variation of time division multiple access (TDMA).

Indoor Propagation Channel: A wireless channel characterized by a high attenuation of the transmitted signal due to internal walls and furniture, a short delay of echo, and a low delay spread. Typically, the distance between transmitter and receiver is short (e.g., both are located in the same building). The temporal variations of the channel are slow compared with outdoor propagation, where a mobile antenna may be mounted on a car.

Localization: Broadly speaking, localization means determining the locality or the position of a given object. The wireless localization is the assignment

of coordinates (consistent with physical location) to nodes in a wireless network.

Mobile Ad-Hoc NETWORKS: (MANET). It is a network of mobile routers (some of them may simply act as a host) that move randomly, communicate by wireless links, and forming an arbitrary topology that can change rapidly, randomly, and unpredictably.

Multilateration: A process by which an object's position is computed based on the time difference of arrival (TDOA) of at least three signals emitted by synchronous transmitters. Not to be confused with with lateration, which uses absolute measurements of time-of-arrival (TOA).

RADAR: A location and tracking system devised by Microsoft, which allows mobile devices equipped with IEEE 802.11 networking technology to use ambient signals to estimate their position. The position is computed either using empirical methods that compare the signal fingerprint with previous measured locations mapped on a radio map, or using a mathematical models of indoor signal propagation.

RSSI: Received Signal Strength Indication. A measurement of the received signal strength (energy integral) by the antenna. The signal strength indicator on a cell phone display is a common example. The higher the RSSI, the stronger the signal.

Signal Fingerprint: Information computed from a received signal that identifies its dependency on the wireless environment. Such information could include received signal strength, multipath pattern of the transmitted signal, TDOA and AOA measurements, signal time delay, or even channel impulse response.

Signal Propagation: The means by which a radio signal flows from a place to another, typically from a transmitting antenna to a receiver antenna.

Spoofing: The process by which an entity (e.g., a program) forges data to impersonate another and gain an illegitimate access or privilege.

UHF: Ultrahigh Frequency. Electromagnetic waves whose frequency ranges from 300 MHz to 3 GHz. Consequently, the UHF wavelengths ranges are between 10 centimeters and 1 meter. The UHF band is widely used by satellites, communication and broadcasting, and cellular phone networks.

UMTS: Universal Mobile Telecommunications Service. The European standard for third-generation mobile telephony. It is envisioned as the successor to Global System for Mobile Communications (GSM) in Europe. Theoretically, UMTS increases the transmission speed to 2 Mbps per mobile, establishes a global roaming standard, and provides simultaneous support for a wide range of services including digitized voice and video, and packet transmission of data.

WCDMA: Wideband Code Division Multiple Access is a third generation (3G) cellular network that uses CDMA technique for multiplexing.

Wireless Mobile Sensor: A device that represents a basic component of a Wireless Sensor Network (WSN). It senses signals to monitor physical conditions (e.g., location, temperature, pressure) at different locations. Typically, it is equipped with a small microcontroller, a source of energy, and a radio transceiver. It should be

of small size and price, so that it can be deployed in large numbers.

INTRODUCTION

In wireless communication, information is carried by electromagnetic waves that propagate in space and can be received by all terminals located within the radio coverage area of the transmitter. This characteristic of wireless communication is often referred to as *broadcast effect*, in which the signal destined to a particular terminal is also received by other terminals and may interfere with their own reception. Such an environment is usually called a *shared medium*, in which a transmitted signal can be overheard by many terminals. Each receiver in a shared medium receives a superposition of the signals transmitted from multiple terminals and destined to distinct receivers. An elaborate multiple-access scheme should be designed to separate the compound signal into its individual components, and extract the signal of interest.

A direct solution to this problem is to modulate the information on a set of orthonormal bases, $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_n\}$, where \mathbf{v}_i is the i th basis vector and n is the dimensionality of the space. Examples of basis vectors include the time slot in *time division multiplexing* (TDM), a frequency band in *frequency division multiplexing* (FDM), a set of orthogonal spreading codes in *code division multiplexing* (CDM), and a cell site in *space division multiplexing* (SDM). In all of these examples, the signal subspace is represented by a set of orthonormal bases,

$$\langle \mathbf{v}_i, \mathbf{v}_j \rangle = \delta_{ij} \quad (1)$$

where $\langle \cdot, \cdot \rangle$ is the scalar product operator, and δ_{ij} is the Kronecker delta function defined as

$$\delta_{ij} = \begin{cases} 1 & \text{if } i = j \\ 0 & \text{if } i \neq j. \end{cases} \quad (2)$$

Using this representation of the signal subspace, the modulation can be defined as an invertible mapping from

the set of source alphabet to the signal subspace. Here, for brevity of discussion, we assume that modulation is performed by multiplying the basis vector by the input data. Therefore, the received signal \mathbf{r} can be represented by

$$\mathbf{r} = \sum_{i=1}^n b_i \mathbf{v}_i \quad (3)$$

where b_i is the data of the i th user. The receiver isolates the signal of interest by computing the scalar product between the compound signal \mathbf{r} and the corresponding basis vector:

$$\langle \mathbf{r}, \mathbf{v}_j \rangle = b_j \quad (4)$$

where we have used equation 1

Unfortunately, in practice it is very difficult to maintain orthogonality among the basic vectors; we usually have

$$\langle \mathbf{r}, \mathbf{v}_j \rangle = b_j + \sum_{i=1, i \neq j}^n b_i \langle \mathbf{v}_i, \mathbf{v}_j \rangle + \mathbf{n} \quad (5)$$

where \mathbf{n} is the background noise. The summation $\sum_{i=1, i \neq j}^n b_i \langle \mathbf{v}_i, \mathbf{v}_j \rangle$ in equation 5 is referred to as the *interference*.

As noticed in equation 5, in multiuser wireless communications, the main sources of error are background noise and interference. The error is pronounced if the noise or interference components in equation 5 are strong. The strength of these components, relative to the signal strength, is usually measured with the *signal-to-interference plus noise ratio* (SINR), defined as

$$\text{SINR} = \frac{S}{I + N} \quad (6)$$

where S is the power of signal, I is the power of interference, and N is the power of noise. If $I \ll N$, the system is noise limited and the interference has minimal or no

impact on the performance of the system. On the other hand, if $I \gg N$, the system is interference limited and noise has a small impact on the performance and can be safely ignored. A major challenge in an interference-limited system is that, unlike noise, which can be overcome by increasing signal power, interference cannot be combated by increasing the signal power. Indeed, increasing signal power will increase interference to other users and will reduce their throughput. In this chapter, we will focus on interference management techniques in interference limited networks.

DS-CDMA Networks

It is well known that *direct-sequence code division multiple access* (DS-CDMA) systems have some desirable features such as dynamic channel sharing, a wide range of operating environments, graceful degradation of the quality of service (QoS), and ease of cell planning. DS-CDMA systems can also support a multiservice mix of services with a broad range of bursty traffic characteristics and QoS requirements.

DS-CDMA systems are interference limited (Viterbi 1995); therefore, multiple-access interference plays an important role in the performance analysis of such systems. Consequently, managing the total interference for all services is a major challenge in multiservice wireless networks (Viterbi 1995). As a result of high bandwidth and simple receivers in user equipments, downlink interference has a more destructive effect than uplink interference. Therefore, in this chapter we will only focus on downlink interference.

Proper utilization of more accurate information on the temporal behavior of the downlink interference can lead to the development of effective resource control mechanisms. However, the conventional approaches for modeling interference in wireless DS-CDMA networks only use the marginal distribution of the total interference (Viterbi 1995; Verdu 1998; Chung and Hanly 2001), and do not consider its temporal behavior. In contrast, here we consider such temporal behavior in multiservice wireless DS-CDMA networks.

Temporal behavior of interference in long timescales for packet data services in a cellular network has been studied in Zhang, Hu, and Shroff (2002) and Zhang and Konstantopoulos (2005), where interference is modeled as a continuous-time process, graceful degradation of the QoS for limited interferences is assumed, and the effects of the call admission procedure are ignored. In Taqqu, Willinger, and Sherman (1997), an ON-OFF process is assumed for user traffic, and the basic concept of heavy-tail processes is utilized to explain the self-similarity of total interference. An ON-OFF process typically refers to the mutually independent, alternating ON periods (during which packets are emitted at a constant rate) and OFF periods (during which no packets are sent). Obviously, this method is not applicable to heterogeneous DS-CDMA cellular networks that support both packet-based and connection-oriented services. In addition to using an ON-OFF traffic model, Zhang and Konstantopoulos (2005), make the following assumptions: the total bandwidth (and as a consequence the number of users) is infinity;

the allocated power to each user is the inverse of the slow-fading channel gain; and a specific wireless channel model is assumed in which the auto-correlation function of channel variations and the transmit power process are of the order of $O(k^{-\alpha+1})$ for $k \rightarrow \infty$, where α is the minimum decay exponent of the tail of the ON and OFF processes. Under these conditions, Zhang and Konstantopoulos (2005), show that the total downlink (and also uplink) interference has asymptotic second-order self-similarity. We will show that, although the heavy-tail assumption of channel auto-correlation function and the infinite bandwidth are relaxed, the total interference depicts asymptotic second-order self-similarity in heterogeneous DS-CDMA networks.

We propose a model for the downlink interference over long time scales and show that it provides significant insight and considerable intuition for designing efficient radio resource control mechanisms. In these time scales, the QoS must be considered over the lifetime of a call/session. For this reason, and for clarity of presentation, we will ignore many physical layer effects because they are pertinent only to much shorter time scales. Rather, we take a simplified model of the lower layers that captures enough of the physical layer characteristics for our purposes, and which has already been successfully used in Viterbi (1995), Chung and Hanly (2001), and Evans and Everitt (1999).

Several system parameters—such as the total number of active users (interferers), their call durations, the allocated power to each call in the corresponding base station, channel variations, and user mobility—cause temporal fluctuation of interference. To model these effects, we take a cross-layer approach in which the traffic characteristics at the application layer and the information on the wireless channels are combined to model the downlink interference.

This chapter focuses on the asymptotic temporal behavior of downlink interference for long time lags, which is essential for efficient predictive/adaptive radio resource control. We show that, for long time lags, the auto-covariance of the downlink interference in a DS-CDMA cellular network with a mix of Poisson and heavy-tail traffics decays subexponentially. This observation indicates that the downlink interference has long-range dependence, and therefore is an asymptotically self-similar process. The predictive nature of the self-similar interference is then utilized to develop a novel cross-layer adaptive-predictive radio resource controller. We use this adaptive-predictive algorithm to estimate the interference fluctuations and then exploit the multi-user diversity (Viswanath, Tse, and Laroia 2002) through the utility-based optimal scheduling.

TOTAL DOWNLINK INTERFERENCE

In this chapter we consider a cellular DS-CDMA network with heterogeneous services. Within this network, the total downlink interference measured at the receiver of a given user is represented by a discrete time process $I(n)$, where n is the time index. For a user in the network coverage area, $I(n)$ represents the average interference over a window of length T_w seconds (the modeling time scale),

with $T_w \gg T_c$, where $1/T_c$ is the spreading bandwidth of the cellular DS-CDMA network. Therefore, $I(n)$ is the sum of the transmitted powers by all base stations, multiplied by the corresponding channel gain from each of those base stations to the user under study, as follows

$$I(n) = \sum_{c=1}^C \xi^c(n) P^c(n) g^c(n) \quad (7)$$

where C is the number of cells in the network, $P^c(n)$ is the total transmit power of the base station in cell c , $g^c(n)$ is the channel gain from the base station in cell c to the user, and $\xi^c(n)$ is the cross-correlation between the spreading sequences of the user of interest and other users. Note that, in equation 7 the power allocated to the user under study is not included in $P^c(n)$. For convenience, we assume that the user is located in cell $c=1$ and that $\xi^c(n)=1$. A nonzero $\xi^c(n)$ in equation 7 indicates that the basis vectors at the receiver are nonorthogonal (c.f. equation 5). To obtain the total interference in equation 7, we first study $P^c(n)$ and $g^c(n)$ separately.

Base Station Transmit Power

In time slot n , each base station serves a set of active users (calls) in its cell coverage area. For simplicity, we assume that each call is served by only one base station. We further assume that each call starts at the beginning of a time slot and that its duration is an integer multiple of T_w . The transmit power of the base station is the sum of allocated powers to all calls in the corresponding cell c . Therefore, $P^c(n)$ is

$$P^c(n) = \sum_{j=1}^J \sum_{i=1}^{N_j^c(n)} p_{ji}^c(n) \quad (8)$$

where J is the number of services provided by the network, $N_j^c(n)$ is the number of calls of service j in cell c at time n , and $p_{ji}^c(n)$ is the allocated power to call i of service j in cell c . For the i th call of service j in cell c , $p_{ji}^c(n)$ has a real value equal to the allocated power over its call duration, and is equal to zero otherwise.

The two random variables at time instant n in equation 8 are $N_j^c(n)$ and $p_{ji}^c(n)$. The number of active calls $N_j^c(n)$ can be uniquely identified by $\mu_j^c(n) \in \mathbb{Z}_+, \mathbb{Z}_+ = \{0, 1, 2, \dots\}$, the number of new call arrivals for service j in cell c at time n , and $\{\tau_{ji}^c, i \in \mathbb{N}\}, \mathbb{N} = \{1, 2, \dots\}$, the call duration sequence process. We assume that for each given cell c and service j , the call duration sequence process, τ_{ji}^c , the arrival rates sequence process, $\mu_j^c(n)$, and the allocated power sequence process, $p_{ji}^c(n)$, are independent random processes, with each being an independent identically distributed (i.i.d.) random process. In the sequel, we denote $\tau_{ji}^c, \mu_j^c(n)$, and $p_{ji}^c(n)$ by the generic random variables $\tau_j^c, \mu_j^c(n)$, and $p_j^c(n)$, respectively. It is straightforward to show that the downlink interference can be completely specified by $p_j^c(n), g^c(n), \mu_j^c(n)$ and τ_j^c , for all j and c (Navaie et al. 2006).

To obtain the characteristics of $P^c(n)$, we need to have the number of active calls for different service types and their corresponding call durations in equation 8 as well as the allocated power over their activity time.

1. *New call arrivals*: In DS-CDMA cellular networks, it has been assumed that no new call arrivals are blocked and no calls are terminated prematurely (Viterbi 1995; Evans and Everitt 1999). This can be justified to some extent by soft blocking of calls in DS-CDMA cellular networks, meaning that there is no hard limit on the number of available channels, and all users suffer from a gradual performance degradation as the load is increased. Here, we assume that $\mu_j^c(n)$ has a Poisson distribution with parameter λ_j^c . Therefore, $\lambda_j^c = E[\mu_j^c(n)]$.
2. *Call durations*: We denote both packet duration and call duration as *call duration* in this chapter. Assume that the call duration is a random variable with a known distribution. Call durations of different service types are assumed to be independent from one another. For voice-only wireless and wireline networks, it is invariably assumed that call durations are exponentially distributed (Viterbi 1995; Kelly 1991). Distribution of call durations in future wireless systems are expected to be similar to the ones in current wireline networks, for which extensive statistical analysis and measurements have established that the distribution of call durations for data and multimedia services are heavy tailed (see, e.g., Erramilli et al. 2002). For a heavy-tailed distribution, the rate of decay of its probability density function is much slower than that of the Poisson distribution. Pareto distribution has been used to model call durations in Erramilli et al. (2002).
3. *Allocated power to each call*: To obtain $p_j^c(n)$, we note that, for a given channel, the allocated power to a given user at time slot n is generally a concave function of its bit rate. Here, for simplicity, we assume that the allocated power is a linear function of the bit rate. We also assume that the system can support any arbitrary bit rate.

Wireless Channel Gain

In equation 7, the transmitted power by each base station is multiplied by the corresponding channel gain $g^c(n)$. To obtain the channel gain, we assume a deterministic distance-dependent path loss and two fading effects: *fast fading* and *shadowing*. Note that fast fading (e.g., Rayleigh or Rician), which is partly canceled out by fast power control, affects $P^c(n)$ in equation 7 in smaller time scales than does the shadowing. Moreover, the short-range effect of fast fading is averaged out in longer time scales such as T_w . Therefore, the channel gain $g^c(n)$ is

$$g^c(n) = L_c d_c^{-\gamma_c} \theta^c(n) \quad (9)$$

where d_c is the distance between the base station c and the user for which the downlink interference is measured; γ_c is the path loss exponent, which is a function of the antenna height and the signal propagation environment; L_c is an environmental constant; and $\theta^c(n)$ is the slow-fading process. Parameter γ_c may vary from slightly less than 1 for hallways within buildings, to larger than 2.5 in dense urban environments and hard-partitioned office buildings (Stuber 1996). The slow-fading process $\theta^c(n)$ has a log-normal distribution with standard deviation σ_c .

The Gudmundson correlation model (Stuber 1996) is used for log-normal shadowing as

$$\Theta^c(n+1) = \rho^c \Theta^c(n) + (1 - \rho^c) \nu^c(n) \quad (10)$$

where the time scale is T_f (fading period), $T_f \geq T_w$, $\Theta^c(n) = \log \theta^c(n)$ is the log-normal fading in dB, $\nu^c(n)$ is a zero-mean white Gaussian noise with variance $\sigma_c^2(1 + \rho^c)/(1 - \rho^c)$, and $0 < \rho^c < 1$ is the channel correlation coefficient.

TEMPORAL BEHAVIOR OF DOWNLINK INTERFERENCE

In this section, we derive the asymptotic temporal behavior of the auto-covariance function of the downlink interference $C(k)$. Using the assumptions of the previous section, it is straightforward to show that the auto-covariance function of $I(n)$ is

$$C(k) = \sum_{c=1}^C \left[C_p^c(k) C_g^c(k) + C_g^c(k) (m_p^c)^2 + C_p^c(k) (m_g^c)^2 \right] \quad (11)$$

where m_p^c and $C_p^c(k)$ are, respectively, the mean and the covariance function of the process $P^c(n)$, and m_g^c and $C_g^c(k)$ are the mean and the covariance function of the channel process $g^c(n)$. Note that here we assume a fast power control mechanism to deal with the undesirable effects of fast fading. Fast-fading and shadowing processes are also assumed to be independent. Therefore, we assume that $P^c(n)$ and $g^c(m)$ are also independent for all n and m .

Before examining the effects of traffic characteristics on the auto-covariance of the downlink interference in equation 11, we need to define regular and slow-varying functions.

Definition 1: A function $f(x) > 0$, $x \in \mathbb{R}$ is called a *regular varying function* (rvf) if there exists an $\alpha \in \mathbb{R}$ (such that for all $u \in \mathbb{R}_+$, $\frac{f(ux)}{f(x)} \rightarrow u^\alpha$, as $x \rightarrow \infty$). The value of α is the *regularity index* of $f(x)$. If $\alpha = 0$, then f is called a *slow-varying function* (svf). We denote \mathcal{RV}_α as the set of regular varying functions such that if $f(x) \in \mathcal{RV}_\alpha$, then $f(x) = L(x)x^\alpha$, where $L(x)$ is an svf (Bingham, Goldie, and Teugels 1987).

A random variable X is said to be heavy tailed with infinite variance if $P(|X| \geq x) \in \mathcal{RV}_\alpha$ for $0 < \alpha < 2$.

Example: Downlink asymptotic temporal behavior (single-cell case): Assume a single-cell system (i.e., $C = 1$) with constant channel gain $g^c(n) = g_0$. For brevity, we drop the cell index in the sequel. Suppose that there are two services (i.e., $J = 2$), both with Poisson distributions for call arrivals with rates of λ_1 and λ_2 . Service $j = 1$ has an exponentially distributed call duration, and service $j = 2$ has a heavy-tail distribution of call durations. Assume further that the call duration of service $j = 2$ has a discrete Pareto-type distribution,

$$\Pr\{\tau_2 = l\} = L_2(l)l^{-\alpha-1}, \quad 1 < \alpha < 2, \quad (12)$$

where $L_2(l)$ is a slow-varying function, and α is the shape parameter of the distribution. A small value for parameter α results in a distribution with a heavier tail. Intuitively, equation 12 implies that there is no typical distribution of call durations (i.e., call durations are highly variable, exhibit infinite variance, and fluctuate over a wide range of values). With these assumptions, it is possible to show that (Navaie et al. 2006)

$$\sum_{k=-\infty}^{+\infty} |C_p(k)| = \infty. \quad (13)$$

This equation indicates that, in case of constant channel gains with heavy-tail distribution of call duration, the downlink interference exhibits extended temporal correlations.

A process whose auto-covariance function satisfies equation 13 is called a *long-range dependent* (LRD) process (Beran 1994). For an LRD process, the correlation between its two samples decreases very slowly with an increase in the temporal distance between those samples. In general, the auto-covariance function of an LRD process for $k \rightarrow \infty$ is $C(k) \sim L(k)k^{-\beta}$, where $L(k)$ is a slow-varying function, symbol ' \sim ' means *behaves asymptotically as*, and $0 < \beta < 1$. In the preceding example, if the distributions of call durations are exponential for both services, their auto-covariance functions are absolutely summable; therefore, the resulting auto-correlation function decays exponentially and creates a *short-range dependent* (SRD) process. The auto-correlation of an SRD process does not have a heavy tail. Note that, for most standard time series, such as auto regressive moving average (ARMA) and Markovian models, the auto-covariance function decays exponentially (Brockwell and Davis 1991), and thus $\sum_{k=-\infty}^{+\infty} |C(k)| < \infty$.

In the preceding example, it is shown that for a constant channel, the heavy-tailed distribution of call durations results in LRD downlink interference. We now extend this observation to more general channel conditions. Assume that the auto-covariance function of the channel process is

$$C_g^c(k) \sim L_g^c(k)k^{-\beta_g^c}, \quad k \rightarrow \infty \quad (14)$$

where k denotes time with a temporal resolution T_w , $L_g^c(k)$ is a slow-varying function, and $\beta_g^c > 0$ is the channel auto-covariance decay exponent. For $\beta_g^c < 1$, the channel process is LRD, and for $\beta_g^c > 1$, the channel process is SRD. In the time scales of interest, this model is consistent with the Gudmundson (1991) correlation model for fading channels.

Proposition 1: For the finite-mean total transmit power process $P^c(n)$, the channel gain $g^c(n)$, and for $k \rightarrow \infty$, $C_p^c(k) \sim L_p^c(k)k^{-\beta_p^c}$ and $C_g^c(k) \sim L_g^c(k)k^{-\beta_g^c}$, the auto-covariance function of the total interference, $C(k)$, satisfies

$$C(k) \sim L^*(k)k^{-\beta^*}, \quad k \rightarrow \infty \quad (15)$$

where $L_p^c(k)$, $L_g^c(k)$, and $L^*(k)$ are svf, and $\beta^* = \min_c \{\beta_g^c, \beta_p^c\}$.

Proof: See Navaie et al. (2006).

SELF-SIMILARITY OF DOWNLINK INTERFERENCE

We now propose an asymptotically self-similar (as-s) model for the downlink interference that extracts the values of its LRD parameters. Let $I(\cdot)$ be a second-order stationary process with a finite mean. We define the aggregate process $I^m(\cdot)$ of $I(\cdot)$ at the aggregation level $m > 1$ by

$$I^m(n) = \frac{1}{m}(I(nm - m + 1) + \dots + I(nm)). \quad (16)$$

The process $I^m(\cdot)$ is obtained from $I(\cdot)$ by partitioning the observation interval into nonoverlapping blocks of size m and averaging $I(\cdot)$ in each block. For each $m > 1$, $I^m(\cdot)$ defines a new second-order finite-mean stationary process. The family $\{I^m(\cdot) : m \geq 1\}$ of aggregate processes is useful for studying the temporal behavior of the total interference at different time scales corresponding to different resource control mechanisms.

A process $I(\cdot)$ is as-s if the correlation coefficients of the average process of block length m as $m \rightarrow \infty$ are identical to those of a self-similar process (Tsybakov and Georganas 1999). A sufficient condition for a second-order stationary process $I(\cdot)$ to be asymptotically self-similar is that for $k \in \mathbb{Z}_+$, $k \rightarrow \infty$, the auto-covariance function of $I(\cdot)$, in other words $C(k) \sim L(k)k^{-\beta}$, in which $0 < \beta < 1$, and $L(k)$ is an svf (Tsybakov and Georganas 1999). Note that an as-s process is also LRD.

Asymptotically Self-Similar Model for the Downlink Interference

We will now develop an as-s model for the downlink interference. Suppose that the total interference is a finite-mean, finite-variance second-order stationary process. We assume that the auto-covariance function of the channel process $g^c(n)$ is as it was in equation 14 for $c = 1, \dots, C$, and $0 \leq \beta_g^c \leq 1$, in which for $\beta_g^c = 1$ the channel process is SRD. In the following proposition, we derive the necessary conditions on traffic and channel characteristics under which the downlink interference is an as-s process.

Proposition 2: Consider the downlink interference process, $I(\cdot)$, and for $c = 1, \dots, C$, let β_p^c satisfy

$$\sum_{j=1}^J \lambda_j^c \Pr\{\tau_j^c = k\} r_j^c(k) \sim L_p^c(k) k^{-\beta_p^c - 2}, \quad k \rightarrow \infty, \forall_c \quad (17)$$

where $r_j^c(k)$ is the auto-covariance function of $p_j^c(n)$ and $L_p^c(k)$ is an svf. Now, $I(\cdot)$ is an as-s process with self-similarity index $H = 1 - \beta^*/2$ if there exists at least one c such that $0 < \beta_p^c < 1$ or $0 < \beta_g^c < 1$, and where $\beta^* = \min_c \min\{\beta_p^c, \beta_g^c\}$.

Proof: See Navaie et al. (2006).

Proposition 2 gives the sufficient conditions for asymptotic self-similarity in the total downlink interference. It combines the service call arrival rate, λ_j , the service call duration distribution, $\Pr\{\tau_j = k\}$, and the correlation function of the allocated power, $r_j^c(k)$, to give the sufficient conditions.

In equation 17, note that if the call duration process of service j^* is heavy tail, then for $k \rightarrow \infty$,

$$\sum_{j=1}^J \lambda_j \Pr\{\tau_j^c = k\} r_j^c(k) \sim \lambda_{j^*} \Pr\{\tau_{j^*}^c = k\} r_{j^*}^c(k). \quad (18)$$

Therefore, we can conclude that the asymptotic behavior of the auto-covariance function of the total downlink interference in a mixed voice and multimedia or packet data, with regular channel variations and regular power transmission, is influenced by providing service to users with heavy-tailed call durations.

MODEL-BASED OPTIMAL DOWNLINK INTERFERENCE PREDICTION

Because the self-similar processes have long-range dependence (Beran 1994), the samples of data in such processes are correlated over long periods. Therefore, a predictor can use a sequence of measured interference samples to precisely estimate the level of interference in future time slots. In this section, we model the total downlink interference with *fractional Gaussian noise* (fGn) and utilize this model to devise an optimal downlink radio resource management scheme (Navaie, Valaee, and Sousa 2005).

If the variance and the self-similarity index, H , of a zero-mean self-similar process are known—subject to assuming an idealized Gaussian setting—the process can be modeled by the fGn.

Definition 2: *Fractional Gaussian noise* (fGn; Beran 1994) is a self-similar Gaussian process with the auto-covariance function

$$\gamma(k) = \frac{\sigma_0^2}{2} (|k+1|^{2H} - 2|k|^{2H} + |k-1|^{2H}), k \in \mathbb{Z}, \quad (19)$$

where σ_0^2 is the variance and H is the self-similarity index.

We assume a large number of users in the coverage area of the network. We also select an appropriate time scale and assume that the resource control mechanism does not alter the total downlink interference model. The interference is then modeled using a fGn process as

$$I(n) = m_I(n) + z(n), \quad (20)$$

where $m_I(n)$ is the average of $I(n)$ measured over the window $(n-L, n-1)$, and $z(n)$ is fGn.

We use the correlation structure of the total received interference and the auto-covariance of fGn, equation 19, to propose the following optimal linear predictor for the total interference (Brockwell and Davis 1991):

$$\hat{I}(n+1) = m_I(n) + (\Gamma^{-1} \underline{\gamma})^T (\mathbf{I}(n) - m_I(n) \mathbf{1}_M), \quad (21)$$

where $\hat{I}(n+1)$ is the predictor of $I(n+1)$, $\mathbf{I}(n) \triangleq [I(n), I(n-1), \dots, I(n-M+1)]^T$ is the $M \times 1$ vector of stored interference measurements, M is the memory length of the predictor, Γ is the covariance matrix with entities $\Gamma_{ij} \triangleq \gamma(i-j)$, $\underline{\gamma} \triangleq [\gamma(1), \dots, \gamma(M)]^T$, where $\gamma(n)$ is given in equation 19, and $\mathbf{1}_M$ is the $M \times 1$ identity vector; the superscript T denotes vector transposition. At a given instant n , the mobile terminal of each user measures the level of interference and adjusts the values of parameters $m_I(n)$, $\sigma_0(n)$, and H . A simple weighted summation of

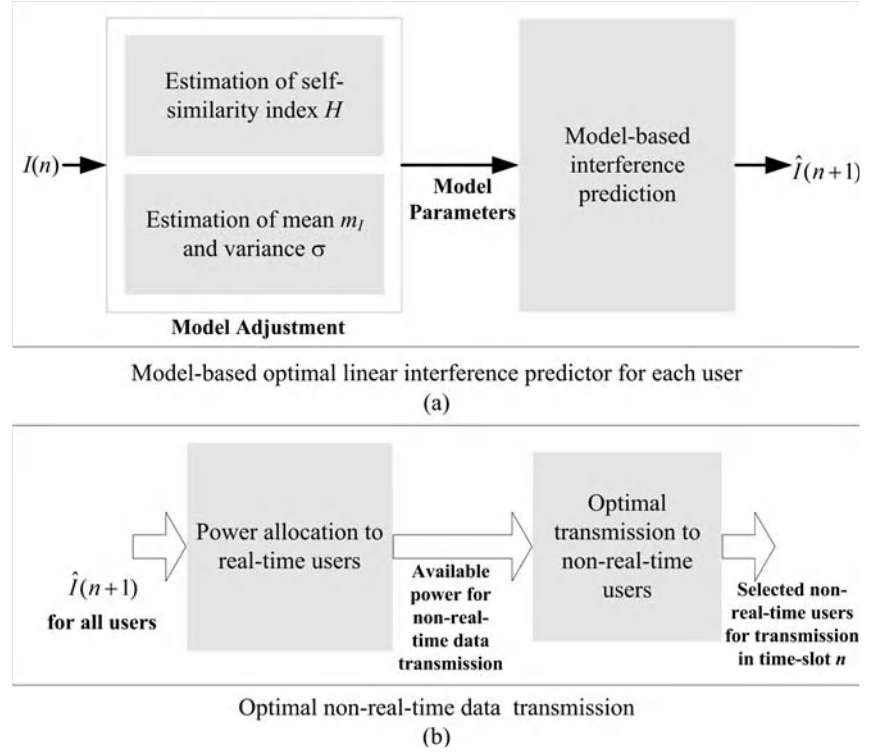

Figure 1: Model-based adaptive-predictive throughput maximization of non-real-time data in the downlink: (a) user module, (b) network

measured values of total interference is used for mean estimation as follows

$$m_I(n) = \frac{1}{M} \sum_{k=n-M}^{n-1} I(k). \quad (22)$$

The interference variance is also estimated by

$$\sigma_0(n) = \frac{1}{M-1} \sum_{k=n-M}^{n-1} (I(k) - m_I(n))^2. \quad (23)$$

To estimate the self-similarity index, H , we use an on-line version of the Abry-Veitch wavelet-based estimator in (Roughan, Abry, and Veitch 2000). This method uses wavelet transformation to perform a weighted least squares fitting for the different octaves, in a multi-resolution platform. The computational complexity for this method is in the order of $O(M)$. The confidence interval of the estimated self-similarity index, \hat{H} , by the Abry-Veitch method is given by

$$\hat{H} - \sigma_{\hat{H}} z_\beta \leq H \leq \hat{H} + \sigma_{\hat{H}} z_\beta, \quad (24)$$

where z_β is the $(1 - \beta)$ quantile of the standard Gaussian distribution—in other words, $P(z \geq z_\beta) = \beta$ —and

$$\sigma_{\hat{H}} = \left(\frac{2}{(\ln 2)^2 2^{-j_1} M} \right) \left(\frac{1 - 2^J}{1 - 2^{-(J+1)}(J^2 + 4) + 2^{-2J}} \right), \quad (25)$$

where $J = j_2 - j_1$, and j_2 and j_1 are two different octaves with $j_2 > j_1$.

Once $m_I(n)$, $\sigma_0(n)$, and H are estimated, they are used in equation 21 to predict the level of interference in the subsequent control window. In view of simplicity of mobile terminals, it would be possible to simply measure

the interference at the mobile terminal, communicate the result back to the base station, adjust the model parameters, and predict the interference in the base station. The base station uses the predicted downlink interference to allocate the available power to non-real-time users.

The variance of the prediction error is: $\epsilon = \gamma(0) - \gamma_1^T \Gamma^{-1} \gamma_1$. It can be shown that the variance of error is not sensitive to the value of M for $M \geq 5$; therefore, the optimal linear predictor can be implemented using a small number of measured interference samples.

The proposed radio resource management procedure is shown as a two-step process in Figure 1. In part a of the figure, an estimate of the interference is obtained. Figure 1b illustrates the hierarchical power allocation process at the base station, where the power is first allocated to real-time users and then the remaining power is distributed among non-real-time users. Note that, in our proposed scheme, the interference predictor in Figure 1a is implemented for all users, including real-time and non-real-time users. This interference predictor can be implemented at the mobile station, at the base station, or at the radio network controller. In each case, the measured interference level, $I_i(n)$, where i is the user index, should be provided to the predictor in appropriate time scales. The base station or the radio network controller then uses the predicted interference levels, $\hat{I}_i(n+1)$, to allocate the transmit power in the next control window.

PERFORMANCE OPTIMIZATION FOR NON-REAL-TIME DATA TRANSMISSION

In this section, we propose two techniques to allocate power to backlogged best-effort traffic. In the first technique, the available power is allocated to users with the

best channel conditions. In such an approach, the users with bad channel conditions may experience excessive delay; hence, the system may have poor delay performance. In the second technique, we use a utility-based approach (Kelly 1997) and propose an optimal utility-based scheduling algorithm to maximize the base-station utility for a given available transmit power.

In the control window n , let $\mathcal{G}(n)$ be the set of real-time users (e.g., voice and multimedia) served with a *guaranteed* delay requirement and $\mathcal{B}(n)$ be the set of delay-tolerant users waiting in the queue to be served under the *best-effort* service category. Because we consider in this section the power allocation in a given cell, hereafter we drop the cell index for brevity.

Power Allocation to Guaranteed Service Users

For a user i in $\mathcal{G}(n)$, with bit rate $R_i(n)$, and the required bit energy to the interference plus noise spectral density, ρ_i , the allocated power should be

$$P_i(n) = \frac{\rho_i R_i(n)}{W g_i(n)} (\hat{I}_i(n) + P_N(n)), i \in \mathcal{G} \quad (26)$$

where $g_i(n)$ is the channel gain between the base station and user i and $P_N(n)$ is the background noise power at the receiver of user i .

We assume that the total transmit power of the base station at instant n is $P_{\max}(n)$. This value may be set either permanently at the network dimensioning phase or adaptively by the radio network controller. Therefore, the available power for non-real-time users in the control window n , $P_A(n)$, is

$$P_A(n) = P_{\max}(n) - \sum_{i \in \mathcal{G}(n)} p_i(n). \quad (27)$$

Next, we distribute $P_A(n)$ among backlogged non-real-time traffic.

Power Allocation to Delay-Tolerant Non-Real-Time Users

Our objective is to find a set of users in $\mathcal{B}(n)$ —namely, $S(n)$ —to maximize the total throughput of non-real-time traffic for a given value of the available transmit power $P_A(n)$ in the n th control window with length T_w . Let $p_i(t)$ denote the allocated power to the i th non-real-time user at time t . The signal-to-interference and noise ratio of non-real-time user i can be written as

$$\text{SINR}_i(t) \triangleq \frac{g_i(t)p_i(t)}{\sum_{j \in S(n), j \neq i} \xi_{ij} p_j(t) g_j(t) + I_i(t) + P_N(t)} \quad (28)$$

where $t \in [(n-1)T_w, nT_w]$, $g_i(t)$ is the channel gain between the base station and user i , and $I_i(t)$ is the total interference received from the adjacent stations and from the signal transmitted to other real-time users in the same cell. The coefficient $0 < \mu_{ij} \leq 1$ is the effective fraction of the received signal power from transmitter j that contributes to the interference experienced by user i .

Define the average rate of user i over control window n by

$$R_i(n) \triangleq \frac{1}{T_w} \int_{nT_w}^{(n+1)T_w} r_i(t) dt \quad (29)$$

where $r_i(t)$ is the instantaneous bit rate defined as

$$r_i(t) = \frac{W}{\rho_i} \text{SINR}_i(t), \quad i \in S(n) \quad (30)$$

where ρ_i is the required E_b/I_0 for user i , and $W = 1/T_c$ is the spreading bandwidth.

The maximum throughput of the non-real-time traffic for a given value of the available transmit power $P_A(n)$ is found from

$$\max_{S(n)} \max_{p_i(t), i \in S(n)} T_w \sum_{i \in S(n)} R_i(n) \quad (31)$$

$$\text{s.t. } \frac{1}{T_w} \int_{nT_w}^{(n+1)T_w} r_i(t) dt = R_i(n), i \in S(n) \quad (32)$$

$$r_i(t) = \frac{W}{\rho_i} \text{SINR}_i(t), \quad i \in S(n) \quad (33)$$

$$\sum_{i \in S(n)} p_i(t) \leq P_A(n), \quad nT_w \leq t \leq (n+1)T_w. \quad (34)$$

Note that, for maximizing the throughput, it is beneficial to allocate the maximum available power over the window $[0, T_w]$. Therefore, equation 34 holds with equality.

It is straightforward to show that the solution to the optimization problem (equations 31 through 34) belongs to the set of *time domain schedulers* (Viswanath, Tse, and Laroia 2002; Berggren et al. 2001; Bender et al. 2000). Generally speaking, time domain scheduling is a scheme in which the total power is allocated to a single user over a fraction of T_w . During this period, the base station transmits only to one user, and the rest of the users are kept inactive. Using time domain scheduling, in equations 31 through 34, a portion of T_w is allocated to a selected user and the base station transmits to that user with transmission power $P_A(n)$. Therefore, in each control window, $S(n)$ includes the users with the best channel condition and backlogged traffic at the base station. Transmission to such users maximizes the total network throughput for a given value of $P_A(n)$. The order of transmission for the users in $S(n)$ during the control window n is not specified by the optimization problem in equation 31.

Delay Fair Resource Scheduling

We assume that each control window of length T_w seconds contains N_f frames of T_f seconds (see Figure 2). Data traffic is packetized into fixed F -bit packets and transmitted

Figure 2: Multi-time-scale system; each control window contains M frames.

in an integer number of frames. At control window n , a number of packets destined to the users in the coverage area are waiting in the base station to be served. The available transmit power, to be allocated to the best-effort service, is $P_A(n)$.

Let $\ell_i(n)$ be the number of required frames for transmission of packet i in control window n ,

$$\ell_i(n) = \left\lceil \frac{F}{R_i(n)T_f} \right\rceil, \quad (35)$$

where $\lceil \cdot \rceil$ gives the upper nearest integer and $R_i(n)$ is the bit rate of the channel to the corresponding destined user. Note that $R_i(n)$ obtained from equation 29 depends on the predicted interference and the channel gain. In practice, variable bit rates are implemented by using the orthogonal variable spreading factor technique (see, e.g., Holma and Toskala 2000). Therefore, only a limited number of choices for $R_i(n)$ would be available.

For packet i , we associate the utility function, $u_i(n)$, which shows the benefit that network earns if the packet is served in control window n . Utility function serves as an optimization objective for packet transmission. It can be used to optimize radio resource allocation to build a bridge among different service and network parameters in different layers. The earned benefit modeled by the utility function provides a priority metric for a packet served by a base station; the larger the value of the utility function, the higher the priority of transmitting the corresponding packet.

The utility function $u_i(n)$ is a function of allocated network resources to that packet as well as its experienced delay. For non-real-time traffic, it is a function of $R_i(n)$ and $d_i(n)$, where $d_i(n)$ denotes the amount of time that the packet has spent in the system. The benefit earned by the base station is an increasing function of the wireless link quality. In addition, for two users with the same channel quality and backlogged packets at time n , it would be more beneficial—from the network point of view—to serve the packet with a larger experienced delay.

For a packet i , transmitted in control window n , we define the following utility function,

$$u_i(n) \triangleq \frac{1}{\ell_i(n)} \exp(d_i(n) - \bar{d}(n)), \quad (36)$$

where $\bar{d}(n) = \frac{1}{N(n)} \sum_{i \in B(n)} d_i(n)$ is the average delay and $N(n)$ is the number of backlogged packets. Note that in equation 36, a packet is given a large utility either when the corresponding user experiences a “good” channel condition or when it experiences a relatively “bad” delay. The utility function in equation 36 is similar to that given in Shakkottai and Stolyar (2002), which attempts to provide fairness in delay. Different utility functions can be designed to satisfy various design objectives. Generally, a utility function is defined by the service provider to quantify the trade-off between the performance (e.g., throughput) and fairness.

We define the total network utility at each control window n as the network performance indicator. Our objective is to maximize the total system utility as

$$\max_{S(n) | P_A(n)} \sum_{i \in S(n)} u_i(n) \quad (37)$$

$$\text{s.t. } \sum_{i \in S(n)} \ell_i(n) \leq N_F. \quad (38)$$

The inequality in equation 38 enforces the system downlink resource constraint. The output of the maximization problem, equation 37, is $S(n)$. Maximization (equation 37) selects the packets that result in the highest total utility, subject to constraint (equation 38). Therefore, at each control window, the solution to equation 37 gives the packets that are scheduled for transmission. Because we solve this optimization problem for each control window, hereafter we drop the time index n for brevity.

Scheduling Algorithm

It is straightforward to show that the optimization problem in equations 37 and 38 is indeed a classical combinatorial problem: the 0–1 Knapsack problem (0–1 KP; Keller, Pferschy, and Pisinger 2004). We note that 0–1 KP is NP-Hard; thus, the exhaustive search solution for KP would be to try all $2^{N(n)}$ cases, where $N(n)$ is the number of backlogged packets at time n . Obviously, such algorithms are not suitable for practical purposes. Instead, we use dynamic programming to solve equations 37 and 38.

Dynamic programming decomposes the optimization problem into smaller problems and then recursively obtains the value of the maximum utility in terms of the solutions to smaller problems (Bertsimas and Demir 2002). Consider the array $U(i : 1, \dots, N, m : 0, \dots, M)$, where N is the number of packets in the base station in the corresponding control window. The entry $U(i, m)$ contains the maximum achieved utility of any subset of packets $\{1, \dots, i\}$ of the total allocated frames m

$$U(i, m) \triangleq \max_{S_i} \left\{ \sum_{j \in S_i} u_j \mid \sum_{j \in S_i} m_j \leq m \right\}, \quad (39)$$

where $S_i \in \{1, 2, \dots, i\}$. The maximum achieved utility is $U(N, M)$. Now, $U(i, m)$ can be defined in terms of the solution to the smaller problems,

$$U(i, m) = \max \{ U(i-1, m), u_i + U(i-1, M - m_i) \}. \quad (40)$$

The pseudo-code of the proposed algorithm is illustrated in Figure 3. In the proposed algorithm, we compute the values of $U(i, m)$ from the bottom up, using equation 40 with the initial condition $U(0, m) = 0$. To keep track of the selected packets for transmission, in Figure 3 we have considered the auxiliary boolean array $s(i, m)$, which is equal to 1 if the decision is to take the i th file in $U(i, m)$, and 0 otherwise. The set of the selected packets for transmission is then constructed using the array $s(\cdot, \cdot)$ by the procedure in the second part of the algorithm in Figure 3.

SIMULATION RESULTS

To study the system performance, we consider a two-tier hexagonal cell configuration with a wrap-around technique (Harada and Prasad 2002). A universal mobile

telecommunications system (UMTS; Holma and Toskala 2000) cellular network, with a fast power controller running at 1500 updates per second, is simulated. Cross-correlation between the codes is assumed to be 0.5. Three traffic types are used: 12.2 kbps voice (with the required $E_b/I_0 = 5$ dB), 32 kbps data (with the required $E_b/I_0 = 3$ dB), and 64 kbps data (with the required $E_b/I_0 = 2$ dB). We assume a steady 5 Erlangs of voice traffic. For data traffic, we assume Pareto call duration. The control window is $T_w = 10$ ms.

We assume that the channel gain $g^c(n)$ is given by equation 9. The Gudmundson correlation model (Stuber 1996) with $\sigma_c = 8$ dB and $T_f = 100$ ms is used for log-normal shadowing. Users are distributed uniformly in the cell coverage area and have different service types. The details of the simulation setting are given in Table 1.

Model Validation

In the aforementioned configuration, we studied the time trace of the received downlink interference measured at different locations. Figure 4 illustrates segments of the received interference time trace (shifted to time 0) in the time scales of $t_s = 100$ ms, 250 ms, 500 ms, and 1s. Measurements were taken at an arbitrary location in cell $c = 1$. High variations are seen in traces of different time scales. A bursty behavior, which is the same for all time scales, is observed. As predicted earlier, the figure shows that the total interference is a self-similar process.

We also estimate the values of the self-similarity index H using the Whittle estimator (Paxson 1995). The Whittle estimator gives $H = 0.65$. Extensive simulations on the

self-similarity in the total downlink interference under different channel and service combinations are also presented in Navaie et al. (2006).

We will now show that fGn is an appropriate model for $I(n)$. We use the quantile-quantile (Q-Q) plot (Beran 1994) to show that the total interference is a Gaussian process. The Q-Q plot is a graphical technique that determines whether two data sets have the same probability distribution. A Q-Q plot is a plot of the quantiles of the first data set against the quantiles of the second data set. A quantile is the fraction of points whose values are smaller than the given value; that is, the x percent quantile is a point at which x percent of the points in the data set have values smaller than the given value and $(1 - x)$ percent have values larger than that value. If the two sets come from a population with the same distribution, the points should fall approximately along the 45-degree reference line. The received total interference values are the first data set, and the values generated by a Gaussian distribution with the same mean and variance are in the second data set. In Figure 5, the Q-Q plot shows that the received total interference for the aforementioned configuration can be closely approximated by the Gaussian distribution.

Figure 5: The Q-Q plot for the marginal distribution of total interference

Performance of the Adaptive-Predictive Method

To study the performance of the proposed method, we add a fourth non-real-time traffic. This traffic constitutes fixed-size packets with Poisson arrival with rate λ . We use a linear predictor with $M = 5$ taps to predict the interference level; we have found that the predictor error is not sensitive to the value of M for $M \geq 5$.

We have run fifty independent simulation trials with users uniformly dispersed in the cell coverage area. In the sequel, we report the average values in these runs for two systems. The first system (System A) uses the proposed method in this chapter for interference prediction. A confidence interval of 95 percent for the estimate of the self-similarity index, H , is considered. For non-real-time traffic, we first consider System A

using the throughput-optimal time domain scheduling (System A-TDS-Th) in equations 31 through 34, and the utility-maximized time domain scheduling in equations 37 and 38 (System A-TDS-U). The second system (System B) uses the average values of the last five samples of the measured interference as the predicted value. We consider System B using the throughput-optimal time domain scheduling (System B-TDS-Th) in equations 31 through 34, and without it (System B-CDMA).

We compare the cell throughput for the non-real-time data service of the systems A and B for different values of the interference self-similarity index H . We consider System B-CDMA as the benchmark and normalize the cell throughput in each case to the corresponding value of the throughput in System B-CDMA. The results are illustrated in Figure 6. A significant improvement in the average cell throughput is seen in Figure 6 where our proposed adaptive-predictive method for interference

Figure 6: The normalized average cell throughput versus H

Figure 7: The standard deviation of the packet delay versus H

prediction is used. As expected, the cell throughput of System A-TDS-U is smaller than that of System A-TDS-Th because we trade the throughput for the delay fairness.

In Figure 6, it is also interesting to note that even for larger values of H , System A-TDS-U outperforms System B-TDS-Th. This is a result of the more accurate interference prediction using our proposed predictive-adaptive method.

We have also found the standard deviation of the actual packet delay for systems A-TDS-U and A-TDS-Th. A small value for the standard deviation indicates fairness in delay. As can be seen in Figure 7, by using the utility-based optimization, the fairness in delay is significantly improved.

An important question to ask is: “What is the impact of applying our proposed method on the self-similarity of interference?” Because the self-similarity of downlink interference emanates from user traffic characteristics, the application of the proposed scheme—and possibly other radio resource control mechanisms—would not alter the self-similarity of the downlink interference; however, it may alter the model parameters. Table 2 illustrates the estimated values of H for the cellular network with the parameters given in Table 1 and with a 95 percent confidence interval after our proposed method is applied. In this table, \hat{H} of five independent simulation runs with different non-real-time packet arrival rates for the

given throughput $R = 5000$ bps are presented. The results in Table 2 confirm the following two points: first, the interference in the downlink is self-similar, as its self-similarity index is greater than 0.5; and second, the self-similarity index does not depend on the arrival rates of non-real-time traffic. This is because the self-similarity in the downlink interference emanates from the traffic characteristics of the real-time calls, which have heavy-tail call durations.

CONCLUSION

In this chapter, we formulated the total downlink interference in a multiservice cellular DS-CDMA network as a stochastic process that depends on the traffic characteristics of users, the transmit power, and the channel variations. We have shown that, under certain conditions, the auto-correlation function of the total interference is a regularly varying function. We further proposed an as-s model for the total interference and derived the conditions for the channel and traffic characteristics under which the as-s model for the total downlink interference is valid. We then used the predictive structure of the total downlink interference to maximize non-real-time data throughput in a multiservice DS-CDMA cellular network. We proposed a model-based linear adaptive-predictive method to estimate the level of interference. The estimated downlink interference of all users is then used in a resource manager to increase the system throughput and minimize the delay for non-real-time data transmission. The simulation studies also confirm that the interference model is valid for a broad range of arrival rates of non-real-time traffic. The self-similarity of downlink interference persists even after the time domain scheduler is applied.

GLOSSARY

Base Station: A physical network element in the radio access network that is responsible for radio transmission and reception to or from the user terminal.

Cross-layer Modeling: *Cross-layer design* refers to a design done by actively exploiting the dependence between different network layers to obtain performance gains. This is in sharp contrast with the layered design, in which functionalities located at different isolated layers are designed independently based on a standard set of outputs provided by lower layers.

Inter System Interference: The received interference originated as a result of the operation of other wireless systems in the same area that share the same set (or part of that set) of radio resources.

Intra System Interference: The received interference originated as a result of the communication to/from other users in that system.

Multi-user Diversity: A potential form of diversity inherent in a wireless network with multiple users, provided by independent time-varying channels across the different users. Multi-user diversity gain is achieved via exploiting delay tolerance of non-real-time traffic to opportunistically schedule the transmission when

Table 2: Estimated H for Different Simulation Runs

	\hat{H} for Different Runs of Simulation				
$\lambda = 5$	0.6431	0.6357	0.6201	0.6520	0.6461
$\lambda = 10$	0.6373	0.6480	0.6542	0.6516	0.6391
$\lambda = 15$	0.6512	0.6439	0.6448	0.6484	0.6435
$\lambda = 20$	0.6405	0.6534	0.6350	0.6282	0.6431

corresponding time-varying channel capacity happens to be at (or near) its peak.

Network Capacity: The number of users in the coverage area that can be supported concurrently by the network with a certain level of QoS. The network capacity is related to different parameters, including radio access network technology, radio transmission characteristics of the network area, users' traffic profiles, and their spatial distribution.

Network Coverage Area: A geometrical area in which radio transmission and reception to or from the user terminal with certain signal quality is achievable.

Radio Resource: In wireless communication, different approaches are utilized to share the scarce wireless medium among multiple users. In most of these approaches, the wireless medium is modeled as a quantity called *radio resource*. Examples of radio resource include the allocated transmit power in DS-CDMA, the number of time slots in time division multiple access (TDMA), and the number of subchannels in frequency division multiple access (FDMA).

Radio Resource Management: A general term for to a set of functions that manage efficient access to the shared radio resource in a multiple-user wireless network. Usually, different functionalities in different network layers are utilized to tackle various dynamics in the corresponding time scales.

Wireless Packet Scheduling: A functionality that manages transmission scheduling to (or from) corresponding users subject to resource and service constraints.

INTRODUCTION

As organizations continue to expand their wide area networks to provide high-availability data access, many are turning to wireless technologies to resolve these issues. However, there is still a general lack of knowledge about the technologies and their associated capabilities. This chapter addresses issues important to identifying appropriate wireless technologies for implementation in enterprise wide area networks.

A *wireless wide area network* (WWAN) is a network that covers a vast area, usually measured in miles or kilometers, and uses the propagation of radio signals to transmit data. At a minimum, it consists of one *access point* (AP) and one client, or subscriber unit, at a remote site. The AP is usually deployed with a connection to a traditional wired network at a company's main office or service provider's central office. The connection is considered broadband with throughput rates greater than 200 Kbps. When microwave transmissions and advanced modulation techniques are utilized, throughput rates can reach 100 Mbps or higher (Wayne and Safran 2000).

Explosive growth in the numbers of network users and their corresponding traffic has resulted in the laying of thousands of miles of fiber-optic cable. However, the vast majority of *Internet service providers* (ISPs) and businesses still use T1's, *digital subscriber lines* (DSLs), or

integrated services digital network (ISDN) connections to transition from *local area networks* (LANs) to *wide area networks* (WANs). WWAN hardware and its applications offer many benefits with little or no increased cost to the consumer. Companies that have implemented WWAN solutions have reported higher initial costs, although the cost of WWAN usage is usually lower over time, with a relatively short return-on-investment period. The main reason for these lower costs is that, once in place, a WWAN usually has no recurring monthly service fees, unlike traditional wireline implementations (such as a T1).

WWAN technologies and implementations have successfully replicated throughputs greater than a T1's 1.544 Mbps and are often ten times this rate or greater. As stated in "Understanding Wireless WAN Communications" (undated), nearly 97 percent of companies in large commercial buildings have no direct fiber access. A WWAN can often bridge the gap between the building and the high-speed fiber connection. As a result, WWANs have been increasingly integrated into the corporate world. WWANs can provide many new services, which will help drive down broadband connection prices for most consumers (Mehta 2004).

As demonstrated by Table 1, a comparative look at existing wireline WAN technologies compared to wireless WAN will reveal the reasons for the explosive growth in WWANs.

Table 1: WWAN Technology Summary

	PSTN	ISDN	T1	DSL	Cable	Fiber	WWAN
Availability	High	Low	High	Growing	Growing	Poor	As needed
Throughput	Poor	Low	Medium	Medium	Medium	Very high	High
Recurring costs	Very low	Medium	High	Medium	Medium	Very high	No: capital only
Right of way required	Yes	Yes	Yes	Yes	Yes	Yes	No
Distance from POP	N/A	5 miles	20 miles	15,000 ft	10 miles	100 miles	30 miles
Voice	Yes	Yes	Yes	Marginal	Marginal	Yes	Yes
Video	No	No	Marginal	Marginal	Marginal	Yes	Yes
Time to market	N/A	Slow	Medium	Medium	Medium	Slow	Fast

WWAN INFRASTRUCTURE

Generally, WWAN implementations fall into one of the following three categories (Intel 2005).

1. **Backhauls:** Point-to-point antennae provide high bandwidth requirements to a single location (similar to a T1 connection). This bandwidth may then be distributed via one of the next two categories of WWANs.
2. **Last mile connections:** Point-to-multipoint antennae connect residential and business subscribers (similar to xDSL or cable).
3. **Large-area coverage access:** Base stations are used to allow mobility and large user counts, often with limited bandwidth (similar to current mobile phone connectivity).

Although using the unlicensed frequency spectrum has obvious benefits (e.g., no licensing fees and lower equipment costs based on the economies of scale), there are times when using licensed bands may be beneficial. Currently, nine bands are set aside for licensed wireless network use (3.7, 6, 7, 8, 11, 13, 18, 23, and 38 GHz), providing significantly more available spectrum than those available within the unlicensed bands. Other benefits of using licensed spectrum include control by the Federal Communications Commission (FCC) to minimize interference in a given geographical area, higher power allotment, and better reliability because of reduced interference. In addition, there is an inherently higher level of security because of the limited-access nature of the licensed spectrum. This makes equipment for the licensed spectrums less readily available, which reduces the chances of “casual” attacks.

The disadvantages of licensed frequency use include paying registration fees to the FCC, higher equipment cost, and the limited availability of frequencies and channels. Typically, equipment based on licensed frequencies is more difficult to install and configure correctly. Table 2 shows typical performance and use of various spectra.

Delivering bandwidth wirelessly between two points is typically done one of two ways: (1) by dedicated backhauls or (2) through the use of distributed mesh topologies. *Dedicated backhauls* are point-to-point links

that use high-bandwidth, low-latency equipment and are commonly configured in a star topology. This application is best suited for areas with clear line of sight between elevated locations such as towers. As more sites are added to increase distances from the location of the wireline central network (or Internet) feed, the cost of implementing dedicated backhaul units and the risk of one outage affecting multiple sites increase exponentially.

An alternative means of providing bandwidth to a distant location is to implement a *mesh topology*. In this configuration, each site can communicate directly with neighboring sites and provide dynamic bandwidth allocation to all sites. This provides additional redundant links between towers and minimizes the risk of a widespread outage. However, this comes at the cost of potential reductions in network bandwidth available to each site. Mesh topology is best suited for areas where line of sight is not available to the main bandwidth distribution points or where high levels of redundancy are essential.

WWAN TECHNOLOGIES

Cellular Providers

The telecommunications industry has changed dramatically since the first telephone company was started in 1877. AT&T, formerly the leading U.S. communications organization since the nineteenth century, no longer provides full service and support to all U.S. users. The industry's focus has shifted from simple connectivity and basic voice conversations to the transmission of voice, data, and information. As technology progresses, new facets of telecommunications are being forged. Light and fiber optics, rather than electricity and copper wires, are the new backbone structures (AT&T 2005). Industry forerunners are pursuing systems that provide mobility, accessibility, reliability, high data rates, and security.

Consumers, both residential and business, seek smaller, more portable, and more versatile devices that increase productivity (AT&T 2005). Mobile wireless devices include *personal digital assistants* (PDAs), new smart cell phones, and laptops that give the user the ability to have data access from anywhere. As a result, telecommunications companies scramble to implement new wireless network technologies to meet consumers' needs.

Table 2: Typical Performance and Uses of Selected Spectrums

Frequency	Bandwidth	Range and Coverage	Flexibility	Typical Uses
900 MHz	Low	High	High	Cordless phones, wireless speakers, wireless remotes, baby monitors, some remote control systems, traffic control systems, supervisory control and data acquisition systems
2.4 GHz	High	Medium	Low	Cordless phones, WiFis, wireless speakers, wireless remotes, Bluetooth, closed-circuit TV, microwaves
5.2 GHz	High	Low	Medium	WiFi, audiovisual repeaters
5.8 GHz	High	Low	Medium	Cordless phones, WiFis, audiovisual repeaters, wireless remotes, baby monitors

The goal of these new mobile wireless technologies is to present voice and high-speed data access anytime and anywhere. The new mobile networks require smart computers and radios, encoding and security, routers and switches, and, most importantly, packet-switched traffic. Packet-switched mobile networks allow all forms of information to be converted and compressed or condensed and then sent to an end user or back to a server. To efficiently and accurately send voice and data, the mobile wireless network must be able to meet the following important criteria (SPG Media Group 2004):

- widespread radio frequency coverage for digital transmission;
- the ability to hand off from location to location, tower to tower;
- high-speed transfers for mobility and accessibility;
- secure, guarded transmission to prevent overlap and bleeding; and
- a variety of terminals (cell phones, PDAs, laptops) that can access high-speed services.

The mobile wireless network technology that is capable of providing all of these features is known as *third generation* (3G). 3G networks can provide voice and data services for public, personal, and business applications (FCC 2005).

The protocol for all 3G communications was defined by the International Mobile Telecommunications-2000 (IMT-2000), a sanctioned standardization development by the International Telecommunications Union (ITU). IMT-2000 was attended by leading technological nations, including the United States, the United Kingdom, Japan, China, and Korea. Together, these nations defined the IMT-2000 as “a framework for worldwide wireless access by linking the diverse systems of terrestrial and/or satellite based networks. It will exploit the potential synergy between digital mobile telecommunications technologies and systems for fixed and mobile wireless access systems” (ITU-R 2005). The three mostly widely distributed 3G architectures presented in IMT-2000 include:

1. *wideband code division multiple access* (W-CDMA), also called *universal mobile telecommunications system* (UMTS), which uses wide direct spread spectrum;
2. *CDMA multicarrier* (CDMA2000); and
3. *time-division multiple access* (TDMA) single carrier (*enhanced data rates for GSM evolution*, or EDGE).

Of the three 3G architectures being implemented, UMTS and CDMA2000 are the most common. These provide for a transition from existing 2 and 2.5G (a step toward 3G that did not provide for the data rates required by 3G). The 3G architecture increases the available data rates, security, and capabilities of all mobile wireless devices that utilize its features.

UMTS is based on the existing GSM and *general packet radio service* (GPRS) architecture. Its features include:

- transfer rates of 144 kbps mobile to 2Mbps fixed (indoor),

- uplink frequencies of 1885–2025 MHz and downlink frequencies of 2110–2200 MHz,
- the W-CDMA protocol for uplink and downlink communications,
- GSM backward compatibility, and
- *subscriber identity module* (SIM) card interoperability from network to network and device to device.

As the 2G technology GSM was being upgraded to UMTS, more innovation was needed to maximize connectivity (UMTS Forum undated). The European Union and the European Telecommunication Standards Institute (ETSI) were already collaborating on development and deployment issues. The partnership had unified companies, including Vodafone, T-Mobile, Mobitel, TIM/Teleset, Belgacom, 3, Tele2, O2, Orange, and Swisscom. With the European providers already embracing fiber-optic networks, a plan was devised to implement the next generation in network addressing: *Internet Protocol version 6* (IPv6) (Cisco Systems undated). Because of the limited number of unique addresses that could be generated by the current *Internet Protocol version 4* (IPv4), only a small number of mobile wireless users would have access to the new packetized data network. IPv6 utilizes hexadecimal numbering (0–9, A–F) to provide an IP address for every network device in the world because of its increased (128-bit) address space. Each new mobile device or user could be issued an IP to be used with mobile terminals. The technology provided maximum access to all networks and users with the ability to swap SIM cards and to port and store terminal information for multiple devices (Vodafone Group 2005).

The mobile wireless initiative in East Asia is particularly expansive, with the three largest users of 3G networks being China, Japan, and Korea. Korea has the greatest concentration of mobile users of any nation in the world. Mobile consumers in these markets have made wireless devices an essential part of their lives. Users manipulate advanced PDAs, smart cell phones, and laptops to access e-mail, online resources, and business applications. The wireless mobile terminals are more than a means of network connectivity, they are tools and instruments.

The landscape of the mobile wireless in Asia is truly 3G. The industry in China and Korea is primarily regulated by the government and several national companies. To compete effectively in the international economic realm, East Asian governments recognized the need to attract more corporate investment and innovation. To make this a reality, the decision to deploy fiber optics throughout these nations was made (Flynn 2005). With a largely rural, agricultural population, China already had a cellular phone base working on the 2G GSM platform. China's Research Institute of Telecommunications developed a partnership with TekTronix to implement that nation's first GPRS network, an interim technology between 2G and 3G. Korea's Telecommunications Technologies Association chose to use CDMA (Telecommunications Technology Association 2001).

In Japan, fiber optics had long been expected to replace copper and wire networks by the mid-1990s. NTT DoCoMo, the leading telecommunications provider in

the country, began its research into 3G in the 1990s (SPG Media Group 2004). The Association of Radio Industry and Business (ARIB) and Telecommunication Technology Committee (TTC), Japan's version of the U.S. FCC and the American National Standards Institute, jointly decided that the 2G CDMA standard would be the framework for its move to 3G. There is speculation that CDMA can also evolve into 3.5G and 4G technologies (with much higher data rates and better mobility). With Vodafone Japan (a subsidiary of the European telecommunications giant Vodafone), DoCoMo began to import 3G innovations for its main testing grounds. Vodafone Japan's implementation used GSM and UMTS technologies. To meet the standard that was set by the TTC and ARIB, Vodafone added cross functionality with CDMA-based networks. NTT DoCoMo introduced the first 2.5G technology, i-Mode, in February 1999. By 2001, DoCoMo and its vendors had worked out most of the problems with i-Mode and began to deploy full 3G to its customer base. The new service, renamed FOMA, was an instant success. By late 2001, DoCoMo's FOMA service had coverage to 90 percent of its customers (nearly 40 million subscribers). As of 2005, 98 percent of the Japan population was covered by DoCoMo's FOMA service, and it continues to grow.

Unlike the European and Asian networks, the American mobile wireless vendors and suppliers lack the unification that aided the European GSM and UMTS movement. There are four major American wireless providers: AT&T Wireless, Sprint Communications Corporation (with Nextel Communications), T-Mobile, and Verizon Wireless (with 45 percent of its financing from a Vodafone Group division). There are also smaller regional providers that pay fees to use the networks of these nationwide mobile wireless carriers. Within these corporations, each has its own private practices, proprietary standards, and, most importantly, 2G technologies (GSM Association 2005). See Table 3.

Although all of these providers are members of the same wireless consortiums, receive terminals from the same vendors, and are regulated by the Federal Communications Commission, these Fortune 500 companies do not generally share research, advancements, or breakthroughs. Although the EU-ETSI partnership actually defined a local, nationwide, and continentwide standards

for use and development, there is no such agreement among these four providers and the FCC.

The four primary carriers have harnessed 2G technologies and are researching and slowly implementing 3G. Cingular has released its GPRS technology, claiming that it has features of 3G but is based on GSM 2G technology. GPRS is often referred to as 2.5G because it is not fully 3G (Wireless Internet Institute 2004). Its features include the following:

- use of GSM (both *time* and *frequency division multiple access*, or TDMA and FDMA) and TDMA technologies to increase data throughput;
- use of four time slots for downlink and one slot for uplink;
- theoretical throughput of 20–200 Kbps;
- division into classes (classes 4, 6, 8, 10, etc.) that use more time slots for downlink and uplink; and
- attempted incorporation of Internet Protocol, point-to-point protocol, and X.25 protocol suite into its connections.

Over time, 2.5G GPRS evolved into EDGE technology (sometimes called 2.75G). EDGE improved on GSM and GPRS techniques, raising speed to 384 kbps. Features of EDGE include:

- 8 PSK (phase shift keying) as modulation for advanced line coding;
- video and multimedia applications and connectivity;
- minimum compliance to the ITU definition of 3G;
- packet-switched, IP connection-based network connectivity; and
- 3G implementation via UMTS.

To counter the GPRS-EDGE technology, Verizon and Sprint independently deployed their 2.5G technology, CDMA2000 1 × Radio Transmission Technology (1 × RTT). The 1 × RTT technology is based on the 2G CDMA, which uses a unique code to allow multifrequency transmission, and 1 × RTT features:

- transmission speeds near 144 kbps;
- growth possibilities to 3.5 and 4G implementations;
- combinations of CDMA 2G frequencies;
- multiple time slots (like GPRS) to manipulate several frequencies and increase downlink and uplink capacities;
- improved quality of voice transmissions and security; and
- 3G implementation of *Evolution Data Optimized* (EvDO).

As of mid-September 2005, the progress of U.S. 3G deployment was as shown in Table 4 (Patterson 2005).

Table 3: Major U.S. Cellular Providers

Carrier	2G Technology (Current)	3G Technology (Future)	International Access
Cingular	GSM	UMTS	Roaming in 170 countries
T-Mobile	GSM	UMTS	Roaming in 140 countries
Sprint	CDMA / iDEN	EvDO / WCDMA	Roaming in 35 countries
Verizon	CDMA	EvDO / WCDMA	Roaming in 11 countries

IEEE 802.16: Broadband Wireless Access

Originally, *broadband wireless access* (BWA) was designed to overcome the distance and load limitations of current DSL and cable networks. Customers outside of the

Table 4: Cellular Providers' Migration Plans and Time Frames

Technology	Provider	3G Migration Plan	Current Availability	Monthly Rates	Nationwide Rollout
GSM	Cingular	UMTS	13 major markets	~\$80/mo	End of 2006
	T-Mobile	UMTS	No	N/A	2007
CDMA	Verizon	1 × EvDO	Most metropolitan markets	~\$60/mo	End of 2006
	Sprint	1 × EvDO	No	N/A	Begin in early 2006

distance and load limitations are unable to use these networks. The high cost associated with running copper or fiber-optic cable to each subscriber location was the driving force behind the initial BWA technologies. As early as 2002, there were an estimated 2400 *wireless ISPs* (WISPs) in the United States using mostly proprietary equipment. The use of this proprietary equipment has limited the cost effectiveness of using BWA technologies (Johnston and LaBrecque 2003).

In mid-1999, the IEEE recognized the need for a broadband wireless access standard. According to the WirelessMAN Working Group (2002), BWA was suffering from a limited reach because of the lack of a universal standard. Seeking to expand the availability of BWA, the IEEE started development of the 802.16 standard, which was approved for publication in December 2001. Since its approval, the 802.16 standard has undergone several amendments and revisions, including 802.16a, 802.16-2004, and 802.16e.

In essence, WiMAX (an acronym for Worldwide Interoperability for Microwave Access) is the practical implementation of the IEEE 802.16 standard. The WiMAX Forum is the nonprofit organization that developed the WiMAX compatibility standards and is responsible for testing and validating the products that are being developed with the WiMAX name. According to the WiMAX Forum (2005) the 10 GHz to 66 GHz specifications are complete and have been submitted to the WirelessMAN Working Group. The 2 GHz to 11 GHz specifications are nearing completion and will be submitted to the working group on completion.

Many of the world's largest telecommunications companies are betting that WiMAX holds the potential to combine the benefits of DSL, 3G, and Wi-Fi networking technologies into one platform and push broadband access into new regions and devices (Hines 2005). Although this may be true, it will be several years before such an infrastructure is in place (Singer 2005). Many public safety and utility applications for WiMAX are also anticipated, including meter-reading tools, traffic monitoring, and video surveillance systems.

According to Fujitsu (2004), the WiMAX Forum has chosen to use the 802.16 mandatory 256 OFDM PHY (i.e., *orthogonal frequency division multiplexing* and *physical layer*) interface as the required technology to receive WiMAX certification. This choice was made to increase interoperability with the European HiperMAN specification, which uses the same 256 OFDM PHY. Fujitsu (2004) stated that the WiMAX Forum is also currently evaluating the encryption options specified by 802.16-2004.

Specifically, they are determining whether to adopt the *advanced encryption standard* (AES) specification as an alternative to the mandatory *data encryption standard* (DES) encryption.

In theory, a single WiMAX base station will be capable of covering a thirty-mile area with speeds as high as 75 Mbps to non-line-of-sight users. This will provide enough bandwidth to support hundreds of simultaneous users from a single base station (Intel 2005). WiMAX has several robust *quality-of-service* (QoS) features built into the protocol. With WiMAX, traffic can be managed based on subscriber's service agreement. The QoS provisioning offers a grant-request mechanism that allocates a portion of each transmitted frame as a contention slot. The contention slot is used to request and uplink a slot from the base station. This method is used to avoid the collisions that are normally seen in a *carrier sense multiple access with collision avoidance* (CSMA/CA) or *collision detection* (CSMA/CD) network with a large number of users (Fujitsu 2004).

The initial design for 802.16 was for last mile communications, providing high-speed data to people in rural areas or in countries with developing infrastructures. According to the WirelessMAN Working Group (2002), the initial 802.16 standard was designed to efficiently use the 10 GHz to 66 GHz bandwidth. The medium access control layer for the standard was designed to support multiple physical layer specifications. Using licensed frequencies in the 10 GHz to 66 GHz range two-way communications with varying levels of traffic can be achieved. The initial standard for 802.16 is restricted to line of sight between the transmitter and receiver, making it useful as a standardized wireless backhaul but not entirely useful for actual subscriber connections (WirelessMAN Working Group 2002).

The 802.16a standard was approved in January 2003. The 802.16a amendment covers medium access control modifications and additional physical layer specifications for 2 GHz to 11 GHz. This amendment includes both licensed and unlicensed bands in the 2-GHz to 11-GHz spectrum (Intel 2005).

The 802.16-2004 revision was ratified in June 2004 and replaces the previous 802.16a standard. As stated in a white paper from Fujitsu (2004), the 802.16-2004 standard specifies three PHY options. A mandatory PHY mode of 256-point OFDM is specified. In addition to the mandatory OFDM PHY layer, single carrier and 2048 *orthogonal frequency division multiple access* (OFDMA) modes are also specified. It should also be noted that the European Standard HiperMAN uses the same OFDM specification.

The 802.16-2004 standard uses duplexing to create bidirectional uplink and downlink channels for data transmission. The standard supports both *time division duplexing* (TDD) and *frequency division duplexing* (FDD). The licensed band solutions use FDD, while license-exempt band solutions use TDD (Intel 2005). Frequency division duplexing requires two channel pairs to reduce interference. One channel is used to transmit, while the other receives. FDD is well suited for voice because of its minimal delay. However, FDD does increase equipment costs because of equipment complexity. Time division duplexing, in contrast, uses a single channel for uplink and downlink. The uplink and downlink time slots can be dynamically allocated, depending on traffic load.

The 802.16-2004 standard also defines specific encryption schemes to be used. The data encryption standard is specified as the mandatory encryption scheme for data, and triple DES is specified for key encryption. The following encryption suites have been specified for use with 802.16-2004 (Fujitsu 2004):

- CBC-mode 56-bit DES, no data authentication, and two-key 3-DES;
- CBC-Mode 56-bit DES, no data authentication, and RSA-1024; and
- CCM-Mode AES, no data authentication, and 128-bit AES.

The 802.16-2004 standard uses spectrum in the 2 GHz to 11 GHz band for both licensed and license-exempt transmission. Table 5 shows the spectra that have been allocated around the world for 802.16-2004 use.

According to Intel's 2005 white paper on deploying license-exempt systems, the 2.5 GHz and 3.5 GHz bands have been selected for licensed use as shown in Table 5, whereas the 5.8-GHz band has been selected for worldwide license-exempt usage. The 802.16-2004 standard supports channel sizes between 1.5 MHz and 20 MHz within these allocated bands.

The WirelessMAN Working Group is currently developing the 802.16e amendment, which will cover physical

Table 5: Spectrum Assigned for 802.16 Deployments

Geographic Region	Spectrum Assigned for 802.16 (GHz)
North America	2.5, 5.8
Asia (Pacific)	3.5, 5.8
Europe	3.5, 5.8
Central and South America	2.5, 3.5, 5.8
Africa and Middle East	3.5, 5.8

and medium access control layers for combined fixed and mobile operation in licensed bands. In short, this amendment will add mobile clients to the 802.16 infrastructure. Mobile clients will be able to hand off between base stations, allowing roaming between service areas. For instance, a city could have several base stations servicing fixed and mobile clients. As a mobile client moves out of the range of one base station and into the range of another, a handoff between the base stations would occur, providing seamless roaming for the mobile client. Figure 1 below shows various WiMAX deployments (Intel 2005).

IEEE 802.20: Mobile Broadband Wireless Access

The 802.20 standard, also known as mobile broadband wireless access, was created to fill in the mobility gaps that 802.16e left behind and to provide global mobility to its users (Table 6). Although the 802.20 standard is still a work in progress, it boasts the ability to have a range as far as 15 km (9 miles). According to Lipset (2003), a user can travel at a staggering 250 km/hr (150 miles per hour) and still maintain a constant connection through its handoff process! This is partially because of the fact

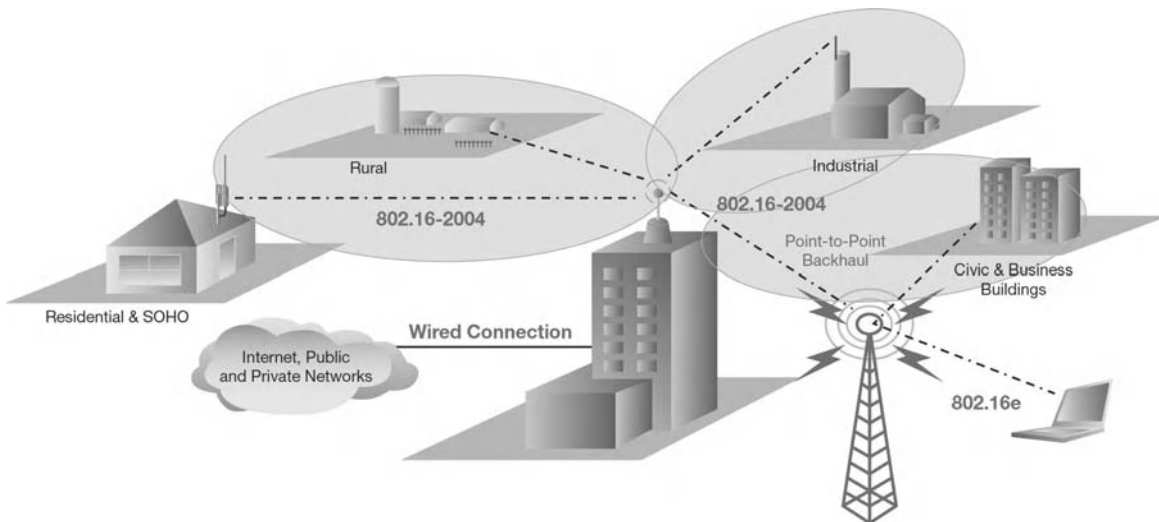

Figure 1: WiMAX deployments

Table 6: Comparison of 802.16e and 802.20

	802.16e	802.20
Type of mobility	Local	Global*
Physical range	1–3 miles	~10 miles*
Maximum velocity for handoff	75 mph	150 mph*
Maximum data rate	~70 Mbps*	16 Mbps
Specified frequencies for use	2–11 GHz*	3–3.5 GHz
Spectral efficiency	5 bps/Hz*	3.2 bps/Hz
Products to market (predicted)	Mid-2007*	2008

*Indicates higher-performing technology.

that the handoff process for 802.20 will have a latency of less than 20 milliseconds. As a result of this, the user will be able to maintain the connection while driving on the interstates or riding bullet trains. The standard will utilize the 3-GHz to 3.5-GHz frequency ranges and will be able to transmit data at 16 Mbps, which is the equivalent of more than ten households or businesses having dedicated T1 connections. According to IEEE 802.20 (IEEE 2005), the connection will be able to utilize four to six different channels and will have a spectral efficiency of 3.2 bps/Hz.

Clearly, 802.16e has many advantages over 802.20, as the WiMAX Forum will agree. In fact, lacking the backing and support of the WiMAX Forum alone may prove to be the end of the 802.20 standard, especially when one considers the dwindling support for 802.20 and the infighting and special interests within the standard's working group. Another advantage that 802.16e has is that the standard-based equipment will most likely enter the market long before the 802.20 standard because many companies such as Intel and CyberTAN have already announced product launches in 2006 and 2007. In contrast to this, Intel announced in 2005 that it would no longer fund research for 802.20 and would most likely not produce chip sets supporting 802.20. This earlier release may be enough to get much wider acceptance and infrastructure in place for 802.16e, thus leaving companies and users doubtful about upgrading to 802.20 equipment when it is finally available several years in the future.

Another advantage for 802.16e is that the standard will be backward-compatible with previous 802.16a infrastructure. On the other hand, 802.20 is not backward-compatible with any previous infrastructure, and all equipment for 802.20 will have to be purchased new at the time of installation. Also, the higher bandwidth that 802.16e provides (70 Mbps) as opposed to 802.20's 16 Mbps is a huge advantage for 802.16e. Many in the United States will say that the high-speed handoffs provided by 802.20 are irrelevant because the United States currently has few high speed trains in place, and most people who drive would not have passengers in their cars to utilize the uninterrupted high-speed connection that 802.20 provides to its users.

WIFI Use as a WWAN

Although originally conceived as an indoor *wireless local area network* (WLAN) technology, it quickly became apparent that 802.11 (WiFi) could be used to cover large outdoor areas or campuses for mobile users and for backhaul and last mile use. In most campus implementations, simply utilizing a high-gain, omnidirectional antenna will provide the necessary coverage area for mobility within that environment. By providing multiple overlapping cells in this way, ubiquitous coverage of a campus can be achieved. Generally, the same access points that are used for a WLAN can be used as the bridge to the wireline network infrastructure (resulting in access to local resources or Internet connectivity), the major difference being the type of antennae used between the two points (Cisco Systems 2005). When used in a wireless backhaul situation, each link end point typically has a high-gain directional antenna installed. The type of antenna used usually depends on the link distance. A Yagi antenna can be used in relatively short link distances of one to two miles, whereas a parabolic dish or grid antenna can be used to establish a link distance of as many as ten miles with clear line of sight. This backhaul configuration could allow the extension of an existing LAN by functioning as a layer 2 bridge, or the backhaul could connect two existing LANs by providing the connection between two layer 2 routers.

Many WISPs have used WiFi as a low-cost method of providing last mile connectivity. Unfortunately, poor network design ("underengineering") has led to many problems with 802.11 WISP successes. Utilizing WiFi as a last mile technology requires line of sight between the two link points. This configuration typically utilizes a high-gain sector antenna (or set of antennae to provide 360-degree coverage) at a centralized locale, and each customer location employs a high-gain antenna. The sector antenna at the centralized locale allows multiple connections from a client device within the coverage area. The customer's parabolic dish or grid antenna allows for a connection directly to one sector antenna. The antennae in this configuration provide a link distance of approximately one mile.

In addition to conventional wireless star topologies, many 802.11 vendors are now offering wireless mesh-based products. As described earlier in this chapter, mesh has many advantages in WWANs. Mesh networks are proving to be extremely useful for municipalities and other providers who wish to cover large areas with increased redundancy and multiple data paths. Each mesh AP, which includes traffic routing functionality, usually uses two different radios operating in two different frequencies. One radio provides coverage for wireless clients, while the other establishes and manages connections to other wireless mesh devices. In this way, the two separate functions are segregated from interfering with one another. Each radio interface on the mesh AP uses an omnidirectional antenna to provide the greatest coverage for connectivity to clients while also maintaining a connection to an adjacent mesh device or set of devices. These wireless mesh access points run a proprietary dynamic routing algorithm that determines the best path through the wireless mesh to an upstream wired network device.

In addition, because each wireless mesh access point does not require a connection to an expensive distribution system, cost savings can be realized versus a traditional wireless access point and wired infrastructure implementation.

CONVERGENCE

Key factors that warrant consideration on the best wireless technology include coverage area, bandwidth requirements, backhaul availability, security needs, and types of end-user devices. By converging multiple technologies, it should be possible to roam from one network to another. For example, because 802.11 currently offers the best indoor data rates and is the most cost-effective to implement in that environment, it only makes sense to use those existing networks for voice and data transport in that environment. As a user leaves the coverage area of the WiFi network, the ideal solution would be to access the next most appropriate (i.e., concerning throughput and coverage) and available wireless network. As 802.16 (WiMAX) becomes more readily available, it would be the next logical network to access with a roaming wireless device. If a WiMAX connection is not available, then transparently accessing one of the cellular providers' 3G networks would be the next logical step. Instead of one wireless technology that provides a constant connection no matter where users are located, using a mix of available technologies (whichever has the best connectivity and throughput at a location) seems to be the next logical step in wireless connectivity.

Security is an important consideration that has demanded attention in recent years. Integration of different wireless network technologies may pose challenging security scenarios. Although cellular networks such as 2.5 and 3G have built-in security features, integrating security with WiFi and WiMAX connections presents a significant and ongoing challenge.

Finally, the end-user device itself has unique requirements in order to function on a heterogeneous network. Although single devices that access multiple different wireless technologies are being introduced, the issues of maintaining a constant session between different networks has not been fully realized. Although protocols such as Mobile IP allow a user to roam across various networks, it will take a significant amount of work to fully implement. In addition, each WiFi network will need to be configured correctly, which is difficult to imagine based on the number of privately owned WiFi networks. Such integration depends on certain business and technical considerations. Business considerations such as service-level agreements and integrated billing systems will need to be implemented. Technical considerations such as interoperability between systems, design, and maintenance will need to be considered as well.

The number of mobile subscribers has increased at a rate that has far exceeded expectations. In 2000, there were 400 million subscribers worldwide; by 2010, worldwide subscribers are projected to reach 2.1 billion users. Wireless traffic continues to shift from traditional voice to multimedia communications. Future services are going to require increasingly larger bandwidth requirements.

The convergence of wireless technologies is critical in managing this increasing demand. The convergence between 3G with WiFi and WiMAX will provide various advantages to both network operators and subscribers. Future mobile systems will provide high quality of service; easy access to high-speed Internet, voice, and video communication; and access to the global positioning system via a single converged device. Several leading companies—including Motorola, Sony Ericsson, T-Mobile, Cingular, AT&T Wireless, and Alcatel—are lobbying the WiFi-Cellular Convergence Alliance to provide standards with respect to billing, roaming, and handoffs. This convergence could be a step toward the promise of 4G wireless systems.

CONCLUSION

Wide area wireless networks can be effectively used to provide high data bandwidth to end users over a large geographic area. WWAN infrastructure can be as simple as a pair of transceivers (such as a single access point and client radio), or it can consist of hundreds of interconnected access points serving thousands of mobile clients. Numerous technologies can be used to construct a wireless wide area network, providing point-to-point and point-to-multipoint connections. WWANs can be used by individuals, companies, municipalities, or service providers as a wire line replacement technology, providing a high level of mobility for high-speed networks. Many WWAN technologies can provide throughput over 100Mbps using radios in the microwave frequencies along with advanced modulation techniques.

The many different types of WWAN technologies will continue to see explosive growth in coming years. The proliferation of cellular 3G networks by wireless service providers will offer users low-cost mobile access to data from many divergent devices, including PDAs, laptop computers, and smartphones. Broadband wireless access, including WiMAX, will increasingly be a viable, cost-effective alternative to wireline network access for residential, business, and municipal use. In many instances, WWANs will be used as a complementary technology to traditional wide area networks, giving network engineers a cost-effective means of providing network connectivity wherever needed.

GLOSSARY

Broadband Wireless Access (BWA): The group of wireless technologies that provide high throughput access to data networks.

CDMA2000: The third-generation (3G) cellular telecommunications standard for voice and data transmission that utilizes CDMA and a pair of 1.25-MHz channels to support peak download rates of 1.5 Mbps.

Code Division Multiple Access (CDMA): A spread spectrum multiplexing technology that utilizes all of the available spectrum and assigns each device a unique pseudo-random code to encode data for transmission.

European Telecommunication Standards Institute (ETSI): A European nonprofit organization that is

responsible for creating standards and documentation in telecommunications, broadcasting, and related areas.

Federal Communications Commission (FCC): The U.S. government agency that is responsible for regulating interstate radio, TV, wire, satellite, and cable communications.

Global System for Mobile (GSM): Formerly titled *Groupe Spécial Mobile*, the 2G cellular telecommunications standard that was created in 1990 to provide quality voice communication and data transfers as high as 9600 bps. GSM and its successors are the most widely deployed cellular systems in the world.

Orthogonal Frequency Division Multiplexing (OFDM): A modulation technique used in 802.11a, 802.11g, and WiMAX in which the digital carrier signal is divided into multiple subcarrier signals that are transmitted simultaneously, reducing channel cross talk.

Universal Mobile Telecommunications System (UMTS): The 3G cellular telecommunications standard developed by ETSI that is capable of providing high-quality voice communications with data transfer rates as high as 2Mbps.

WiMAX Forum: The nonprofit consortium of organizations that define compliance standards and testing and validation methods for device certification.

Wireless Fidelity (WiFi): The industry term for the IEEE802.11 standards, typically 802.11b/g.

Wireless Wide Area Network (WWAN): The use of digital radio equipment to provide a dedicated point-to-point connection or point-to-multipoint connections that typically span distances greater than 400 meters.

Worldwide Interoperability for Microwave Access (WiMAX): The industry implementation of the IEEE802.16 standards.

INTRODUCTION

Recently, wireless broadband access (WBA) has emerged as a very active research area in the wireless communications community. As its name implies, a broad definition for wireless broadband access is “accessing broadband services wirelessly.” Using this definition, WBA technologies bear two important characteristics features. First, they have to be able to operate wirelessly, such that the services can be provided without the need for wired connections. Second, they should be able to offer wireless services at a sufficiently wide bandwidth, over which many content-rich services can be included. In this sense, many wireless services available now can in general be viewed as WBA applications, which may differ from one another in terms of the size of their coverage areas and their capabilities to support mobility, as long as they can provide sufficient bandwidth. For instance, different third-generation (3G) mobile cellular systems, based on either CDMA2000 (1xEV-DV) or W-CDMA (high-speed downlink packet access [HSDPA]), can provide a bit rate of at least 2 Mbps, which is enough to support many data communication applications, such as Internet browsing, file upload and download, video conferencing, and so forth. The 3G infrastructure can be viewed as a type of WBA technology that supports mobility and covers a relatively large area. On the other hand, recently emerging ultra-wideband (UWB) can offer wireless connections to various stationary or portable terminals in a small area with a typical radius less than twenty meters. The data transmission rate of a UWB system can reach 500 Mbps or higher, making it an ideal means to provide wireless broadband access for personal digital assistants (PDAs) external data storage units, and other equipment that requires high-speed data transfer with little mobility support. Therefore, the UWB is also a WBA technology in a broad sense. Similarly, we can find many other currently available wireless services that can also be classified as wireless broadband access technologies.

On the other hand, the WBA technology can also be defined in a narrow sense, such that it is usually referred to as a particular kind of wireless networking technology that should cover a relatively large area (at least a few kilometers in radius) and is able to provide point-to-multipoint or point-to-point wireless access. Using this narrow definition, the WBA technology works like a wireless version of x digital subscriber line (xDSL) technologies to provide wideband access to houses, buildings, and other premises as an alternative “last-mile” or “first-mile” solution. Some WBA technology (such as that specified in the Institute of Electrical and Electronics Engineers (IEEE) 802.16e standard) can support mobile terminals at a vehicular speed. A typical example of WBA technology using this narrow definition is IEEE 802.16 standards, also commonly called wireless metropolitan area networks (WMANs) or Worldwide Interoperability for Microwave Access (WiMAX) technology. A similar technology called wireless broadband (WiBro) has also been developed in Korea.

In this chapter, we try to follow the broad definition to discuss the issues of wireless broadband access technology in general. However, some emphasis will be given to the introduction of WiMAX technology. The content covered in this chapter aims to offer readers both a global view of wireless broadband access and sufficient coverage of WiMAX technology.

While discussing WBA technology broadly, we will review the different wireless networks and standards currently available. IEEE 802.11, wireless local area networks (WLANs) and wireless fidelity (WiFi) are ideal for isolated “islands” of wireless connectivity; WiMAX (WMANs) and 3G (wireless wide area networks [WWANs]) are needed for long-distance wireless coverage. Meanwhile, some people believe that WiMAX and 3G are both required because their optimum platforms differ: WiMAX works best for computing platforms, such as laptops and notebook

Table 1: Different Wireless Networking Technologies for Different Applications

Technology	Standard	Use	Data Rate	Range	Frequency
UWB	802.15.3a*	WPAN	110–480 Mbps	<30 feet	7.5 GHz
WiFi	802.11a	WLAN	<54 Mbps	<300 feet	5 GHz
WiFi	802.11b	WLAN	<11 Mbps	<300 feet	2.4 GHz
WiFi	802.11g	WLAN	<54 Mbps	<300 feet	2.4 GHz
WiMAX	802.16d	WiMAX	<75 Mbps (20 MHz bandwidth)	Typically 4–6 miles	Sub 11 GHz
WiMAX	802.16e	Mobile WiMAX	<30 Mbps (10 MHz bandwidth)	Typically 1–3 miles	2–6 GHz
W-CDMA	3G	WWAN	<2 Mbps (<10 Mbps in HSDPA)	Typically 1–5 miles	1.8, 1.9, 2.1 GHz
CDMA2000 1xEv-DO	3G	WWAN	<2.4 Mbps	Typically 1–5 miles	400, 800, 900, 1700, 1800, 1900, 2100 MHz
EDGE	2.5G	WWAN	<348 Kbps	Typically 1–5 miles	1.9 GHz

*The IEEE 802.15.3a group was disbanded very recently, after the completion of the draft of this book chapter.

computers, whereas 3G is best for mobile devices like PDAs and cell phones. On the other hand, the UWB offers very short-range wireless connectivity, perfect for home entertainment environments, wireless USB, or IEEE 1394. Therefore, each technology is important for different reasons with regard to providing general wireless broadband access, as shown in Table 1.

This chapter is outlined as follows. In the next section we will briefly introduce the history of wireless broadband access technologies, focusing on the standardization process of IEEE 802 Task Groups in making various wireless networking standards. The following five sections will discuss WLANs, wireless personal area networks (WPANs), WMANs, WWANs, and wireless regional area networks (WRANs), respectively. Although this chapter covers different wireless data networks, we spend more time discussing WMANs (or WiMAX) to acknowledge the important role WMANs play in wireless broadband access technology. The chapter concludes with a brief summary.

THE ROAD TO WBA

The development of wireless broadband access technologies is closely related to the historical background of wireless data networks in general. In this section, we will discuss the history of the first data network and concentrate on the role played by the standardization processes of various IEEE 802 standards.

Pioneer Wireless Network: ALOHANET

The history of wireless data networks can be traced back at least to the early 1970s, when a pioneer wireless data network project, called ALOHANET, was carried out at the University of Hawaii. The research project on

ALOHANET acted like a testbed to develop a wireless packet radio network, which formed a basis for today's all-Internet protocol (IP) wireless networks. The objective for the ALOHANET project was to offer a wireless data-link connection among different campuses located on the different islands of Hawaii, to facilitate the data communications needed to exchange information, and to connect different remote data terminals with the mainframe computers situated in the central campus.

In ALOHANET, a very basic medium access control (MAC) protocol was used, which works in a random multiple-access scheme to allow all users to share the common communication resources in both time and frequency domains. Therefore, it works in a way that is similar to code division multiple access (CDMA) in terms of their capability to share resources in both time and frequency. However, the difference between the two is that ALOHANET usually will not guarantee successful simultaneous transmissions (due to collision) even if the number of active users is less than the system capacity; in CDMA, all simultaneous transmissions will be successful as long as the number of active users is limited to the system capacity. The most important feature of random multiple-access techniques is its suitability for supporting burst-type traffic (i.e., all traffic will be delivered in short packets, whose transmissions do not need an end-to-end circuit connection, to realize the connectionless information delivery). This in particular is well suited for IP-based wired and wireless networking applications. All random multiple-access-based networks offer services to users on a best effort basis, in which not all traffic will always be successful, but a relatively high resource-sharing efficiency can be achieved working in a packet-switched operation mode.

The random multiple-access scheme is one of the most widely used MAC protocol designs in today's

all-wireless data networks. The simplest random multiple-access scheme is pure ALOHA, which originated from ALOHANET. It works in a very simple manner: when a packet is coming to a transmitter in the ALOHA system, it will just send it into the channel. The fate of the sent packet will depend on the status of the receiver, which should be located within effective radio coverage of the transmitter. If the receiver is busy (either busy transmitting or busy receiving from another transmitter), the sent packet will be ignored and the transmitter will realize the failure of the transmission after a fixed delay, which should be made longer than any possible turnaround time of the channel (which should be more than twice as long as the one-way propagation delay between the transmitter and the receiver). Then, the transmitter should resend the same packet after a random delay called back-off time, which is used to avoid a series of collisions due to possible transmissions from two or more transmitters that retransmit at the same time. The transmitter will continue the same process until it succeeds in sending this packet. The packet transmissions in a pure ALOHA system are illustrated in Figure 1. On the other hand, if the intended receiver does receive the packet from the transmitter successfully, the receiver should send back an acknowledgment, which will be used as a token of successful transmission by the transmitter.

Network Standardization by IEEE

The wide proliferation of wireless data networks can be facilitated by standardization of the technologies; otherwise, the compatibility would be a serious problem when end-user terminals move from one network to another, which may be designed by different vendors. Many international organizations have been actively pushing for the standardization of wireless data networks, including WBA technologies. Because of space limitations, in this chapter we concentrate on the discussion of various IEEE 802 standards for wireless data networks in general, although many other organizations are also working hard to make numerous standards for wireless networking, such as the European Telecommunications Standard Institute (ETSI), and others.

The IEEE is a nonprofit, transnational, technical professional organization with over 350,000 members. IEEE

supports many activities, including conferences, publications, and local chapter functions. In addition, IEEE carries out an active program in standardization through the IEEE Standards Association (IEEE-SA). Although many IEEE-SA activities are global in scope, its efforts are accredited by the American National Standards Institute (ANSI). ANSI's oversight ensures that its guiding principles of consensus, due process, and openness are followed. IEEE-SA standards are openly developed with consensus in mind. Participation in their development and use is entirely voluntary. However, history has shown that standards developed in an open forum can produce high-quality, broadly accepted results that can focus companies and forge industries. The IEEE-SA oversees the standardization process through the IEEE-SA Standards Board. Project development is delegated to individual standard sponsors that are generally units of the IEEE's technical societies.

In fact, the IEEE develops and maintains technological standards based on the recommendations of individuals, with their expertise in the technology being standardized. Scientists, manufacturers, and end users provide input to the institute, which comes to a consensus about the standards suitable for a particular technology. Use of an IEEE standard is wholly voluntary, and the existence of an IEEE standard does not imply that there are no other ways to produce, test, measure, purchase, market, or provide goods and services related to the scope of the IEEE standard (IEEE 802.11 1999). Research scientists, manufacturers, and end users all benefit from the shared specifications contained in the standards. When everyone uses the standard, customers can use equipment from different manufacturers with no incompatibilities.

Here, we are interested in particular in the set of IEEE 802 standards that have a lot to do with the physical (PHY) and data-link layers of local and metropolitan area networks. These are the bottom two layers in the International Organization for Standardization (ISO)/open system interconnection (OSI) networking model, which are far from the application layer and are concerned with data transmission (and reception) between computers in LANs and MANs. The IEEE has split the data-link layer into two different sublayers: logical link control (LLC) and media access control, as shown in Figure 2. The IEEE

Figure 1: Illustration of random or uncoordinated transmissions of packets in ALOHANET in Hawaii in the early 1970s; five users (A, B, C, D, and E) exist, and any packets overlapped in time are collided

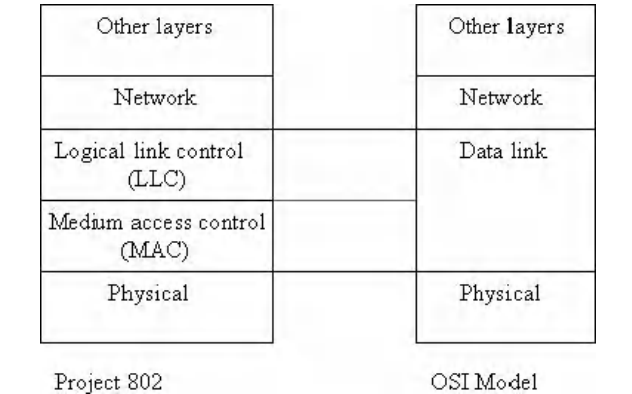

Figure 2: MAC sublayer and LLC sublayer split in IEEE 802 standards (Forouzan 2001)

Table 2: IEEE 802 Standards List

802.1	Higher-layer LAN protocols
802.2	Logical link control
802.3	Ethernet (wired)
802.4	Token bus
802.5	Token ring
802.6	Metropolitan area networks (MANs)
802.7	Broadband
802.8	Fiber optic
802.9	Isochronous LAN
802.10	LAN/MAN security
802.11	Wireless LAN: 2.4 GHz or 5 GHz band
802.12	Demand priority
802.13	Not used
802.14	Cable modem
802.15	Wireless PAN
802.16	Wireless broadband access (WBA)
802.17	Resilient packet ring
802.18	Radio regulations
802.19	Coexistence
802.20	Mobile wireless broadband access
802.21	Handover and interoperability in heterogeneous networks
802.22	Wireless regional area networks (WRANs) in TV bands

LLC protocol concerns the logical address, control information, and data portions of a high-level data-link control (HDLC) frame, whereas the MAC protocols deal with synchronization, error control, and physical addresses. The MAC protocols, such as the random multiple-access protocol discussed in the previous section, are specific to the LAN using them (e.g., Ethernet, token ring, token bus, etc.; Forouzan 2001).

Various IEEE 802 series standards were developed to offer technical standard references, which all people can follow on a volunteer basis. All widely quoted IEEE 802.x (where x can be equal to 1 to 22) standards are listed in Table 2. Not all IEEE 802.x standards were developed inclusively for wireless data networks, let alone for wireless broadband access networks. For instance, the IEEE 802.3 standards are concerned with Ethernet (often wired) communications. Originally, they supported 10 Mbps data rates, but as network terminals became faster and thus capable of running multimedia applications, and as the need to share high-speed servers among LANs became widespread, faster data rates were included in the standards. They were updated in the mid-1990s to include “fast Ethernet” transmission rates of 100 Mbps, and in the late 1990s the Gigabit Ethernet was standardized under 802.3 (Pahlavan and Krishnamurthy 2002). Experts attest that the two major drives of this industry have always been the ease of installation and the increase in data rate, the two

important characteristics of Fast Ethernet and Gigabit Ethernet. Thus, Ethernet dominated other 802.3 LAN IEEE standards (the token ring and token bus).

Here, we are obviously interested in the IEEE 802.11, which specifies a series of standards on WLANs; the IEEE 802.15, which specifies a series of standards for WPANs; the IEEE 802.16, which specifies a series of standards for WMANs; the IEEE 802.22, which is a newly established standard project under the IEEE 802 group aimed at providing WRAN; and WWANs, which are usually implemented by cellular mobile networks. In the subsequent sections, we will discuss the context of wireless broadband access technology.

WIRELESS LOCAL AREA NETWORKS (WLANs)

Of all IEEE 802 standards, those for WLANs specified in IEEE 802.11 standards are by far the most widely seen in the literature concerning wireless networks. The main reason is that the applications of WLANs have been flourishing, and business related to WLANs has been going extremely well, as can be seen from the great number of hot spots that exist on the streets of any major city in the United States, Japan, and Europe.

The IEEE 802.11 technology comprises a series of standards, ranging from IEEE 802.11a to IEEE 802.11w,

Table 3: IEEE 802.11 Wireless Local Area Networks (WLANs)

802.11a	Wireless LAN: 5 GHz band
802.11b	Wireless LAN: 2.4 GHz band
802.11c	Wireless LAN: Higher layers
802.11d	Wireless LAN: MAC
802.11e	Wireless LAN: MAC, QoS, including packet bursting
802.11f	Higher layers
802.11g	Wireless LAN: Higher-rate 2.4 GHz band
802.11h	Wireless LAN: MAC based on cognitive radio
802.11i	Wireless LAN: MAC
802.11j	Wireless LAN: Japanese spectrum 4.9 and 5 GHz
802.11k	Wireless LAN: With radio resource measurement
802.11l	(Reserved, typologically unsound)
802.11m	Wireless LAN: Maintenance of the standard
802.11n	Wireless LAN: Higher throughput improvements
802.11o	(Reserved, typologically unsound)
802.11p	WAVE (DSRC) — Vehicular wireless access
802.11q	(Reserved, typologically unsound)
802.11r	Fast roaming
802.11s	ESS mesh networking
802.11t	Wireless performance prediction (WPP) — test methods and metrics
802.11u	Interworking with non-802 networks
802.11v	Wireless network management
802.11w	Protected management frames

as shown in Table 3. There are approximately twenty different IEEE 802.11 standards, each representing a specific wireless local area network technology/architecture. With a typical data rate between 11 Mbps and 54 Mbps, WLANs can also be considered a wireless broadband access technology that can provide many diverse data services, including Internet applications, video conferencing, and other multimedia options. Therefore, it is justified to discuss WLANs under the context of WBA technology, which is the focus of this chapter.

When developing the standards for wireless networks, the IEEE observed the radio frequency regulations of the U.S. Federal Communications Commission (FCC), because radio waves were the transmission medium of choice for wireless networking. In 1985, the FCC designated certain portions of the radio frequency spectrum for industrial, scientific, and medical (ISM) use, and these became known as the ISM bands, which include (1) 902 MHz–928 MHz, a bandwidth of 26 MHz; (2) 2.4 GHz–2.4835 GHz, a bandwidth of 83.5 MHz, commonly called the 2.4 GHz band; and (3) 5.725 GHz–5.850 GHz, a bandwidth of 125 MHz, commonly called the 5 GHz band. Within certain guidelines, the FCC's regulations allow users to operate radios inside these bands without an FCC license, an obvious boon for the developers of wireless network technology

(and for the users who do not have to obtain a license to operate their cell phones).

The 802.11 standards have evolved over time, and presently six methods for wireless data transmission are defined in the 802.11 standards. Each means of transmission represents its own physical layer design within a certain 802.11 standard. The first IEEE 802.11 standards were completed in 1997 and defined three of these physical layers for 1 and 2 Mbps data rates. An overview of these PHY layers is provided in Table 4 and also explained as follows.

1. The direct sequence spread spectrum (DSSS) physical layer uses the 2.4 GHz band and can transmit data at 1 or 2 Mbps. The DSSS technique was first used for military communications. To prevent jamming and, to a lesser extent, eavesdropping, radios that use DSSS transmit their signals across the entire available ISM band at very low power. This prevents interference from narrowband signals (jammers or others) and lessens the likelihood of transmission errors. Eavesdroppers may interpret these signals as background noise (IEEE 802.11 1999).
2. The frequency hopping spread spectrum (FHSS) physical layer also uses the 2.4 GHz band for transmission

Table 4: IEEE 802.11 Physical Layers

DSSS	2.4 GHz	1 or 2 Mbps
FHSS	2.4 GHz	1 or 2 Mbps
DFIR	850 to 950 nm (infrared)	None implemented
COFDM	5 GHz	54 Mbps
HR/DSSS	2.4 GHz	5.5 or 11 Mbps
OFDM	2.4 GHz	54 Mbps

at 1 or 2 Mbps, and also originated in military applications. Two communicating radios using FHSS change frequencies according to a predetermined pseudo-random pattern, and only remain on a given frequency for a split second (FCC regulations require the frequency hops to take place every 400 milliseconds or less). This technique minimizes the chances that more than one radio device will be transmitting on the same frequency at the same time. If a sender happens to detect interference from another radio at a particular frequency, it retransmits its data after the next hop to a different frequency. FHSS was phased out of 802.11 in the 802.11b standards.

3. The diffused infrared (DFIR) physical layer uses near-visible light in the 850 nm to 950 nm range for signaling (IEEE 802.11 1999). However, unlike infrared TV remote controls that need a line of sight to work, devices that follow the 802.11 DFIR standards do not need to be aimed at one another, permitting the construction of a true LAN (IEEE 802.11 1999). But, there are no wireless networking products currently available that implement this physical layer [17]. One potential source of interference when using this technology, for example, is a human being walking between a personal computer (PC) and its printer when they were trying to communicate.
4. The fourth 802.11 physical layer is defined by IEEE's 802.11a standards: the coded orthogonal frequency division multiplexing (COFDM) layer is capable of transmitting data at 54 Mbps by using the broader 5 GHz band. However, FCC regulations limit the transmission power used at these higher frequencies and thus reduce the distance higher-frequency transmissions can travel. For these reasons, radios that use COFDM technology must be closer together than those using the other physical layers introduced earlier. The obvious benefit of COFDM is speed. Cognitive radio technology has been introduced to allow IEEE 802.11a networks to operate even under potential mutual interference. This led to a new standard, called IEEE 802.11h, which applies two important elements of cognitive radio technology—dynamic frequency selection (DFS) and transmit power control (TPC)—to constantly monitor the environment to avoid possible interference to the primary users.
5. The IEEE 802.11b standards cover the fifth physical layer, the high-rate direct sequence spread spectrum (HR/DSSS) layer. Using this layer, data can be

Table 5: IEEE 802.15 Wireless Personal Area Networks (WPANs)

802.15.1	WPAN: Bluetooth
802.15.2	WPAN: Coexist with WLANs
802.15.3	WPAN: Ultra-wideband (UWB) technology
802.15.4	WPAN: ZigBee and low-speed WPANs
802.15.5	WPAN: Mesh networking (not finalized)
802.15.6	WPAN: Ultra-fast WPANs (not finalized)

transmitted at 5.5 or 11 Mbps, rivaling the standard Ethernet rate of 10 Mbps; as a result, this has become the most widely used IEEE 802.11 physical layer despite only entering the scene in 1999. HR/DSSS technology is an extension of DSSS technology and is designed to be backward compatible with its predecessor (both operate in the 2.4 MHz band).

6. The sixth 802.11 physical layer is detailed in the IEEE 802.11g standards and is backward compatible with 802.11b. The orthogonal frequency division multiplexing (OFDM) physical layer allows 54 Mbps data rates in the 2.4 MHz band. The speed of transmission under OFDM and COFDM is sufficient to carry voice and image data fast enough for most users, and thus to provide wireless broadband access to end users.

WIRELESS PERSONAL AREA NETWORKS

The WPAN technologies can also be considered one of the ways to provide wireless broadband access, depending on the real bandwidth a WPAN can work with. The specifications of WPANs are given under the IEEE 802.15 standard series, and the different WPANs standards are listed in Table 5.

IEEE 802.15.1 Standard

The 802.15.1 standards define the PHY and MAC layers for small, short-distance wireless networks. The core technology specified in IEEE 802.15.1 is largely based on Bluetooth technology. The term *personal operating space (POS)* is introduced in the standard to refer to the small area covered by a WPAN. Defined by IEEE terms, a POS is the space around a person or object that typically extends up to 10 m in all directions and envelops the person, whether stationary or in motion. The IEEE 802.15.1 standards have been developed to ensure coexistence with all IEEE 802.11 networks (IEEE Part 15.3 2003). The 802.15.1 WPANs may operate in the 2.4 GHz ISM band (IEEE Part 15.3 2002), which is the same as that in which the IEEE 802.11 networks operate. Therefore, the IEEE 802.15.1 standards put forth a lot of effort to avoid possible mutual interference between the WPANs and other networks operating in the same unlicensed ISM band.

Much of this standard is derived from Bluetooth core, profiles, and test specifications (IEEE Part 15.3 2003). The objective is to make the 802.15.1 WPANs capable of

employing Bluetooth devices, if desired. The terms *Bluetooth WPAN* and *IEEE 802.15.1 WPAN* refer to the specific and single example of a WPAN presented in this standard series (IEEE Part 15.3 2003). According to the standards, an IEEE 802.15.1 WPAN can be viewed as a personal communications bubble around a person. Within this bubble, which moves as a person moves around, personal devices can connect with one another. These devices may be under the control of a single individual or several people's devices that may interact with one another (IEEE Part 15.3 2003).

Unlike the traditional devices used in WLANs, 802.15.1 WPAN devices often include digital cameras, PDAs, and global positioning system (GPS) units—the devices that run on batteries—which are generally more mobile than the servers, client computers, and printers found on a WLAN. Therefore, the 802.15.1 standards define smaller power levels and area coverage for WPANs (around 10 m) than for WLANs (around 100m). In addition, whereas WLANs generally have an unending life span, the life span of a WPAN is for as long as a master device participates in the WPAN (IEEE Part 15.3 2003). The 802.15.1 standards permit the WPANs to connect to 802.11 WLANs or 802 (wired) LANs, if desired (IEEE Part 15.3 2003).

802.15.1 WPAN uses fast frequency-hopping (F-FH) CDMA for its multiple-access technology, which implies that the hopping rate is much greater than the symbol rate. The Bluetooth standard employs frequency hops fixed at $2402 + k$ MHz, where $k = 0, 1, \dots, 78$, with a nominal hop rate of 1600 hops per second. This results in a single hop slot of 625 microseconds. The modulation scheme used in IEEE 802.15.1 is Gaussian prefiltered binary frequency shift keying (FSK).

The Bluetooth specification has a raw data rate of 1 Mbps. However, because of the overhead reserved for the various Bluetooth protocols, the available net data rate is approximately 723 kbps. Bluetooth can support an asynchronous data channel, up to three simultaneous synchronous voice channels, or a channel that simultaneously supports asynchronous data and synchronous voice. Each voice channel is a synchronous link allowing 64 kbps in each direction. The asynchronous channel can support an asymmetric link of up to 723.2 kbps in either direction while permitting 57.6 kbps in the return direction, or a 433.9 kbps symmetric link. The actual data rates depend on the kind of error-correction capability employed, which is a characteristic of the type of packets being transferred ("Short Description of Bluetooth" n.d.).

IEEE 802.15.3a Standard

If IEEE 802.15.1 is not viewed as a fully qualified wireless broadband access technology because of its limitation of the highest data transmission rate, the IEEE 802.15.3a standard can be considered a WBA technology, at least in its broad definition, with its highest data rate being able to reach 500 Mbps.

The IEEE 802.15.3 standard defines low-cost and low-power-use protocols for high-speed (up to 500 Mbps) WPANs. UWB technology is supported, including ad hoc piconet formation and disassembly. The speed is meant to satisfy user multimedia needs (IEEE Wireless MAC

and PHY Specifications n.d.). Low power use is ensured with protocols that either allow the WPAN to establish a (low) power setting for its devices, or allow communicating devices with a good connection to lower their power as long as the connection remains strong (IEEE Wireless MAC and PHY Specifications n.d.).

The core of the IEEE 802.15.3a standard is the UWB technology, which can be viewed as a derivative of spreading spectrum technology, in particular the time-hopping spread-spectrum (THSS) technique, which is also considered a multiple-access technology, being particularly suited for extremely narrow pulse transmissions. Before discussing the technical details of the UWB technologies, we would like to review briefly the history of the UWB technologies as well as the recent research activities carried out in this area.

Since the introduction of UWB technology to commercial applications in the early 1990s (Fullerton 1991), much of its initial research has focused on the applications of THSS (Win and Scholtz 2000), in which several pulses in each symbol duration are sent with a particular time offset pattern that is predetermined by a unique signature code for multiple access. The implementation of a THSS UWB system requires a precise network-wide synchronization clock. This inevitably increases overall hardware complexity at a transceiver, which used to be a major concern with regard to realizing a feasible UWB system at its early stage. On the other hand, direct sequence (DS) techniques can also work jointly with UWB systems to provide multiple access among different users within the same WPAN. The operation of a DS-UWB system does not need an accurate synchronization clock. The use of antipodal pulses in DS modulation can boost effective transmission power, which is very important to improve detection efficiency of a UWB receiver because of the severe emission constraints imposed on power spectral masks specified in the FCC Part 15.209, in which the maximal transmitting power for a UWB transmitter should be lower than -41.3 dBm within the bandwidth from 3.1 GHz to 10.6 GHz.

In September 1998, the FCC issued a notice of inquiry (NOI), and, within a year, the Time Domain Corporation, U.S. Radar, and Zircon Corporation had received waivers from the FCC to allow limited deployment of a small number of UWB devices to support continued development of the technology. In addition, the University of Southern California (USC) Ultra Lab received an experimental license to study UWB radio transmissions. In May 2000, a notice of proposed rule making (NPRM) was issued by the FCC. In April 2002, after extensive commentary from the industry, the FCC issued its first report and order on UWB technology, thereby providing regulations to support deployment of UWB radio systems. This FCC action was a major change in the approach to the regulation of radio frequency (RF) emissions, allowing a significant portion of the radio frequency (RF) spectrum, originally allocated in many smaller bands exclusively for specific uses, to be effectively shared with low-power UWB radios.

The FCC regulations classify UWB applications into several categories with different emission regulations in each case. Maximum emissions in the prescribed bands are at an effective isotropic radiated power (EIRP) of -41.3 dBm per MHz, and the -10 dB level of the emissions must

Figure 3: FCC regulated spectral masks regarding the indoor and outdoor UWB communications applications

Figure 4: Other communications applications in the vicinity of UWB operating bands

fall within the prescribed band, as shown in Figure 3, which should be compared with Figure 4 to recognize other communication applications in the vicinity of the UWB operating bands.

It will be very interesting to summarize different types of UWB technologies suggested so far under the context of the IEEE 802.15.3a standard. There are four major UWB technologies that have been proposed. The first type is time-hopped (TH) or time-modulated (TM) UWB, which is a traditional UWB scheme that is often called impulse radio (IR) UWB. The TH-UWB is by far the earliest version of UWB technology and remains an important solution even today. The traditional impulse radio technology can be called as either time-hopped or time-modulated UWB; both names are widely used. The TH-UWB can be further divided into two subcategories, analog impulse radio multiple access (AIRMA) and digital impulse radio multiple

access (DIRMA), which were suggested in Win and Scholtz (1998a, 1998b, 2000). The second UWB technology is direct-sequence CDMA-based UWB, as discussed earlier, and can be implemented with a multi-carrier CDMA architecture. Another UWB scheme that has gained much popularity is based on OFDM technology, namely OFDM-UWB, which can be implemented on a multiband (MB) OFDM scheme. The MB-OFDM UWB technology is particularly useful when cognitive radio technology will be used. In addition, some people also proposed frequency-modulation (FM)-based UWB systems, which can be implemented by swept frequency technology. Figure 5 shows a family tree for all possible UWB technologies that have been proposed so far. Depending on the techniques a UWB uses, the IEEE 802.15.3a standard can offer a data rate from 20 Mbps up to 500 Mbps. Without a doubt, IEEE 802.15.3a can be considered a WBA technology under its broad definition.

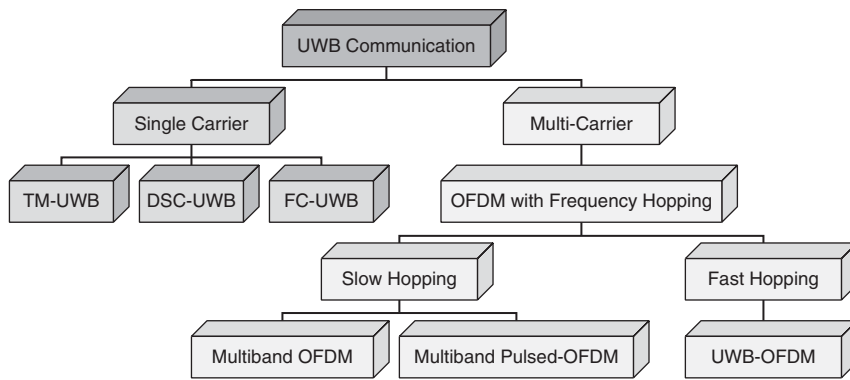

Figure 5: Family tree for various UWB technologies

Figure 6: Conceptual view of an IEEE 802.16-based WMAN

WIRELESS METROPOLITAN AREA NETWORKS

WMANs are always considered as a means to provide wireless broadband access to houses, buildings, and other premises as an alternative last-mile solution to wired xDSL technology. IEEE 802.16 is the most important WMAN standard developed to address wireless broadband access applications to link commercial and residential buildings to high-speed core networks and thereby provide access to those networks. IEEE 802.16's work has primarily aimed at a point-to-multipoint topology with a cellular deployment of base stations, each tied into public networks and in contact with fixed wireless subscriber stations. The subscriber stations typically include rooftop-mounted antenna/radio units connected to indoor network interface units, although in some cases both units could be indoors or both outdoors. Initial work has aimed at businesses, with much of the market focus on small- to medium-sized enterprises. Attention has increasingly turned toward residential opportunities, particularly as the lower frequencies have become available for two-way service. Additionally, potential applications for IEEE 802.16 WMANs include deployment in vast rural areas in both developed and developing countries.

A conceptual view of an IEEE 802.16-based WMAN is shown in Figure 6, in which a WMAN base station is mounted on top of the higher building to service several lower buildings/houses through wireless broadband

access air-link. The base station is usually connected to fixed wideband networks. IEEE 802.16 series standards give technical specifications for WMANs, also commonly called WiMAX technologies.

History of IEEE 802.16 Standard

The activities of IEEE 802.16 standardization were initiated by activity of the National Wireless Electronics Systems Testbed (N-WEST) at the U.S. National Institute of Standards and Technology (NIST). The N-WEST organized a kickoff meeting at the 1998 IEEE Radio and Wireless Conference (RAWCON). Altogether, forty-five delegates accepted an invitation to meet with the IEEE 802 Working Group in November 1998, and IEEE 802 then approved the formation of a study group. That group met twice and wrote the Task Group 1 project authorization request (PAR). The Working Group's first session took place in July 1999. At that meeting, the Task Group 2 PAR was approved by IEEE 802. In November 1999, IEEE 802.16 created the study group that developed the Task Group 3 PAR, which was subsequently approved in March 2000. At that time, a study group for the license-exempt bands was set up and developed the acronym WirelessHUMAN (wireless high-speed unlicensed metropolitan area network) to describe the standard effort. The Task Group 3 PAR was approved in December 2000. Currently, IEEE 802.16 has 137 members, 74 potential members, and 59 official observers. Its work has been closely followed; for example, the IEEE

802.16 Web site received over 2.8 million file requests in the year 2000. IEEE 802.16 maintains close working relationships with standards bodies in the International Telecommunications Union (ITU) and ETSI, particularly with the high performance radio access (HIPERACCESS) and high performance radio metropolitan area network (HIPERMAN) programs of ETSI's Broadband Radio Access Networks (BRAN) project and with ETSI Working Group TM4. Several publications provide additional detail about those activities (Foerster and Sater 2000; Petry 2001).

The standardization of IEEE 802.16 technology took a progressive path, which is continuing even today. The process for IEEE 802.16 standardization learned a lesson from the IEEE 802.11 standards before it. Some consider the original IEEE 802.11 (WiFi) specifications a dismal failure. Initially, in order to grab the early market share, all of the vendors interpreted the specifications differently. A great deal of wireless LAN equipment was on the market well before there were IEEE 802.11 standards. However, it was very expensive, and there was no interoperability. With that in mind, WiMAX is already far ahead of the game. WiMAX has a standard, and the IEEE 802.16 Task Group has worked to figure out how to support WiMAX and make it grow on a long-term basis. The IEEE 802.16 Task Group helps bring all the information together that vendors and carriers can work with. Therefore, the standardization process for IEEE 802.16 is really a success story, especially when compared to IEEE 802.11.

The IEEE 802.16a was approved by the IEEE in January 2003 and is basically an amendment to the more general 802.16 core standard developed in December 2001 by IEEE Task Group 1. The core 802.16 specification was an air-interface standard for wireless broadband access systems using point-to-multipoint infrastructure designs, and operating at radio frequencies between 10 GHz and 66 GHz. It targeted an average bandwidth performance of 70 Mbps and peak rates up to 268 Mbps. However, that standard was not complete in many peoples' minds. It applied only to line-of-sight deployment in licensed spectrum, neglecting to offer any conformance guidelines and ignoring ongoing development of the similar European HIPERMAN standard. The IEEE was working quickly, as it typically does, and with 802.16a it built more functionality into that original draft. The 802.16a collection of amendments took into account the emergence of licensed and license-exempt broadband wireless networks operating between 2 GHz and 11 GHz, with support for non-line-of-sight (NLOS) architectures that could not be supported in higher frequency ranges. Support for NLOS performance was one of the primary physical layer differences in 802.16a, which was developed with the requirements of lower frequencies.

In 802.16a, there were actually three new PHY-layer specifications: a single-carrier layer, a 256-point FFT OFDM layer, and a 2048-point FFT OFDMA layer. The 256-point waveform is the one that is employed in both WiMAX and the ETSI's HIPERMAN standard, ensuring worldwide interoperability. The amended standard also allowed for WiMAX deployment in varying channel capacities to address the different amounts of spectrum carriers own from market to market, and in different parts of the world. The inclusion of TDD and FDD duplexing schemes

was yet another positive move for the technology's international potential. Beyond the additions at the PHY layer, the 802.16a version made further enhancements to the MAC layer, which uses a slotted TDMA uplink/downlink protocol between the WiMAX base station and the subscriber terminal. This type of intelligent scheduling of user access to the network improves latency, affecting the network capability to support voice and video services, and overall service reliability. Other quality of service (QoS) features include automatic retransmission request (ARQ), per-connection QoS, and automatic power control. IEEE 802.16a offers a better set of MAC and PHY profiles to work with compared to IEEE 802.16 standard.

Although 802.16a does much to improve on the original standard, the core standard has had enough amendments attached to it that the IEEE redrafted the specification. The new standard, referred to as 802.16 Revision D, was ready in the third quarter of 2004. The new core specifications included everything that changed about the standard after the 802.16 standard was issued. However, the evolution of the WiMAX standard would not be complete with 802.16 RevD. In December 2005, the IEEE proposed IEEE 802.16e, another new amendment that introduced mobility into what WiMAX proponents hope will be a thriving market for broadband wireless.

The standardization process for IEEE 802.16-based WiMAX continues even today. An important step for the latest WiMAX technology is its introduction of cognitive radio technology to address the needs to operate in some licensed bands with incumbent users, which are the primary users of the bands. This version of WiMAX will be included in IEEE 802.16h, which is still on its way to becoming new standard.

Why WiMAX?

The initial motivation to propose WiMAX technology was to overcome the deployment difficulties of broadband wired access for Internet and other data-centric applications. The demands for broadband data access are driven by wide applications of Internet services. As shown in Table 6, worldwide Internet users constitute approximately 14.6 percent of the total population, meaning that almost one-sixth of the world's total population are Internet users. From this data, we can see how important the Internet is in today's world.

To deliver the Internet services to every household, the broadband data access capability is a must. Currently, there are three common ways to provide fixed-line broadband data access. One is to use fixed wideband optical fiber cables, also called *fiber to home*. This approach has been used in many new buildings and is relatively expensive to carry out. Another common way to provide the fixed broadband data access is to use relatively cheap and already-existing telephone lines with the help of xDSL technology to provide every household with broadband data access. The xDSL has in fact become a default standard technology for offering broadband data access in many countries throughout the world because of fixed-line infrastructure and relatively low cost to implement in virtually every home. The third method to implement fixed-line broadband data access is to use existing cable TV transmission systems via

Table 6: Top Twenty Countries with the Most Internet Subscribers (2005)

Country	No. of Subscribers	Population in 2005	Penetration Rate	World Percentage
United States	202,888,307	296,208,476	68.5 %	21.6 %
China	103,000,000	1,282,198,289	7.9 %	11.0 %
Japan	78,050,000	128,137,485	60.9 %	8.3 %
Germany	47,127,725	82,726,188	57.0 %	5.0 %
India	39,200,000	1,094,870,677	3.6 %	4.2 %
United Kingdom	35,807,929	59,889,407	59.8 %	3.8 %
South Korea	31,600,000	49,929,293	63.3 %	3.4 %
Italy	28,610,000	58,608,565	48.8 %	3.0 %
France	25,614,899	60,619,718	42.3 %	2.7 %
Brazil	22,320,000	181,823,645	12.3 %	2.4 %
Russia	22,300,000	144,003,901	15.5 %	2.4 %
Canada	20,450,000	32,050,369	63.8 %	2.2 %
Spain	15,565,138	43,435,136	35.8 %	1.7 %
Indonesia	15,300,000	219,307,147	7.0 %	1.6 %
Mexico	14,901,687	103,872,328	14.3 %	1.6 %
Taiwan	13,800,000	22,794,795	60.5 %	1.5 %
Australia	13,784,966	20,507,264	67.2 %	1.5 %

Malaysia	9,513,100	26,500,699	37.9 %	1.1 %
Rest of the World	176,943,950	2,444,250,712	7.2 %	18.8 %
World Total	938,710,929	6,420,102,722	14.6 %	100.0 %

a set-top box, also called a *cable modem*, to connect to Internet services. Obviously, all aforementioned broadband data access technologies have serious limitations in the sense that they all rely on fixed-line infrastructure, without which the broadband data access would not be possible.

On the other hand, wireless broadband access does not require any forms of fixed-line infrastructure; it can work as long as a WBA subscriber station connected with fixed public wideband lines is installed (a couple miles away from the point at which the WBA services are required) and a set-top box transceiver is available at home. Therefore, the WBA technology has clear advantages in terms of operational readiness and implementation flexibility to provide point-to-multipoint and point-to-point wireless broadband access services, which can range from normal voice calls to multimedia applications such as real-time video conferences and so on. This unique characteristic of the WBA makes it a must for all natural disaster rescue missions and other emergency operations. The recent Hurricane Katrina rescue operations in New Orleans have shown its usefulness and effectiveness.

General Features of WBA

WiMAX is a certification mark for products that pass conformity and interoperability tests for the IEEE 802.16

standards. Products that pass the conformity tests for WiMAX are capable of forming wireless connections between them to permit the carrying of Internet packet data. WiMAX is similar to WiFi in concept but includes certain improvements that are aimed at enhancing performance and should permit usage over much greater distances. IEEE 802.16 is Working Group number 16 of IEEE 802, specializing in point-to-multipoint WBA.

Before we address the general features of wireless broadband access, we would like to take a closer look at WiMAX. WiMAX is a broadband wireless point-to-multipoint (although it can also be used for point-to-point applications in general) specification from the IEEE 802.16 Working Group. Unlike wireless LAN technologies such as WiFi (IEEE 802.11), WiMAX is designed to operate as a wireless MAN. This places WiMAX in the same class as the earlier 802.16 standards, multichannel multipoint distribution service (MMDS) and local multipoint distribution service (LMDS). As WiMAX technology matures, both MMDS and LMDS will be replaced by much more advanced WiMAX systems, which can deliver the same services in a much more cost-effective way. WiMAX can operate in both FCC-licensed and non-licensed bands. Licensed WiMAX operates in the 10 to 66 GHz range; unlicensed WiMAX operates in the 2 to 11 GHz range.

Table 7: IEEE 802.16 WBA Technologies (WMANs or WiMAX)

802.16a	WBA: For 2–11 GHz band, up to 70 Mbps, NLOS
802.16b	WBA: Quality of Service (5–6 GHz)
802.16c	WBA: Interoperability (10–66 GHz)
802.16d	WBA: Builds on 802.16c (2–66 GHz)
802.16e	WBA: Mobility support (2–6 GHz)
802.16f	WBA: Builds on 802.16e to improve multihop functionality
802.16g	WBA: Efficient handover and improved QoS
802.16h	WBA: Cognitive radio technology

Under the umbrella of IEEE 802.16 standards, there are eight different standards, as shown in Table 7, from IEEE 802.16a to IEEE 802.16h (where every letter represents a different amended WMAN standard).

What Makes WiMAX Different from WLAN

Although WLANs can also provide wireless broadband data access to users with a respectable data throughput (from 11 Mbps to 54 Mbps), WMANs usually cover a much larger area, which can be as large as thirty kilometers in radius, depending on the traffic models and data-transmission rate requirements. Therefore, WBA covers not only a local area but a metropolitan area, just as its name suggests in WMAN. To understand this point is a clear distinction must be made between a WLAN and a WMAN, which can be rather confusing. As previously mentioned, we would like to consider WBA technology a general networking technology that provides wireless data access to end users.

There is another important distinction between IEEE 802.16 WMANs (WiMAX) and other wireless networking technologies, such as WLANs. WiMAX allows multiple frequency bands operation to send payload data to the end users, such that it can effectively avoid possible interference to the other existing wireless applications and thus can enhance the communication quality. This important feature has been implemented specifically in IEEE 802.16h, which works based on cognitive radio technology and uses intelligence to understand the operating environment, such that it can shift to another frequency band when it knows that existing primary users are in the same band.

In addition, WiMAX offers a scalable data transmission throughput management scheme to adjust the use of available frequency spectrum depending on the data-rate requirements from different users. For instance, if a user demands a relatively high transmission rate, the use of OFDM technique can increase the data throughput by dividing a relatively wide service band into many narrow subcarrier channels for parallel transmission. Based on current standard specifications, a WiMAX system can fully support many different transmission modes, such as IPv4, IPv6, Ethernet protocol, asynchronous transmission mode, and so on. Its effective coverage area can reach as far as thirty miles with its uplink and downlink transmission

speed of 75 Mbps, which is great enough to carry any multimedia contents in its wireless bit pipe.

WiMAX Major Operational Advantages

The major operational advantages for WiMAX technology can be summarized as follows.

1. WiMAX offers a flexible architecture.

WiMAX supports several system architectures, including point-to-point, point-to-multipoint, and ubiquitous coverage. The WiMAX MAC supports point-to-multipoint and ubiquitous service by scheduling a time slot for each subscriber station (SS). If there is only one SS in the network, the WiMAX base station (BS) will communicate with the SS on a point-to-point basis. A BS in a point-to-point configuration may use a narrower-beam antenna to cover longer distances.

2. WiMAX can work in a very high security level.

WiMAX supports advanced encryption standard (AES) and triple data encryption standard (3DES). By encrypting the links between the BS and the SS, WiMAX provides subscribers with privacy (against eavesdropping) and security across the broadband wireless interface. Security also provides operators with strong protection against theft of service. In addition, WiMAX has built-in VLAN support, which provides protection for data that are being transmitted by different users on the same BS.

3. WiMAX provides scalable QoS requirements.

WiMAX can be dynamically optimized for the mixture of traffic that is being carried. Four types of service are supported: (a) unsolicited grant service (UGS), which is designed to support real-time data streams consisting of fixed-size data packets issued at periodic intervals, such as T1/E1 and voice over IP; (b) real-time polling service (rtPS), which is designed to support real-time data streams consisting of variable-sized data packets that are issued at periodic intervals, such as MPEG video; (c) non-real-time polling service (nrtPS), which is designed to support delay-tolerant data streams consisting of variable-sized data packets for which a minimum data rate is required, such as FTP; and (d) best effort (BE), which is designed to support data streams for which no minimum service level is required and that can be handled on a space-available basis.

4. WiMAX is suitable for quick deployment.

Compared with the deployment of wired solutions, WiMAX requires little or no external plant construction. For example, excavation to support the trenching of cables is not required. Operators that have obtained licenses to use one of the licensed bands, or that plan to use one of the unlicensed bands, do not need to submit additional applications to the government (in particular the case in the US). Once the antenna and equipment are installed and powered, WiMAX is ready for service. In most cases, deployment of WiMAX can be completed in a matter of hours, compared with months for other solutions.

5. Multilevel service is available in WiMAX.

The manner in which QoS is delivered is generally based on the service-level agreement (SLA) between

the service provider and the enduser. Further more one service provider can offer different SLAs to different subscribers, or even to different users on the same SS.

6. Interoperability is another important advantage of WiMAX.

WiMAX is based on international, vendor-neutral standards, which make it easier for endusers to transport and use their SS at different locations, or with different service providers. Interoperability protects the early investment of an operator because it can select equipment from different equipment vendors, and it will continue to drive the costs of equipment down as a result of mass adoption. WiBro technology developed by Korea will eventually be harmonized with WiMAX to make them fully compatible with each other.

7. WiMAX is a technology with great portability.

As with current cellular systems, once the WiMAX SS is powered up, it identifies itself, determines the characteristics of the link with the BS (as long as the SS is registered in the system database), and then negotiates its transmission characteristics accordingly.

8. Mobility is supported in WiMAX.

The IEEE 802.16e amendment has added key features in support of mobility. Improvements have been made to the OFDM and OFDMA physical layers to support devices and services in a mobile environment. These improvements, which include scalable OFDMA, MIMO, and support for idle/sleep mode and hand-off, will allow full mobility at speeds up to 160 km/hr. The WiMAX Forum-supported standard has inherited OFDM's superior NLOS performance and multipath-resistant operation, making it highly suitable for the mobile environment.

9. WiMAX can operate in a cost-effective way.

WiMAX is based on an open, international standard. Mass adoption of the standard, and the use of low-cost, mass-produced chipsets and handsets, will drive costs down dramatically, and the resultant competitive pricing will provide considerable cost savings for service providers and endusers.

10. WiMAX offers wider coverage.

WiMAX dynamically supports multiple modulation levels, including BPSK, QPSK, 16-QAM, and 64-QAM. When equipped with a high-power amplifier and operating with a low-level modulation (e.g., BPSK or QPSK), WiMAX systems are able to cover a large geographic area when the path between the BS and the SS is unobstructed.

11. Non-line-of-sight operation is allowed in WiMAX.

NLOS usually refers to a radio path with its first Fresnel zone completely blocked. WiMAX is based on OFDM technology, which has the inherent capability of handling NLOS environments. This capability helps WiMAX products deliver broad bandwidth in a NLOS environment, which other wireless product cannot do.

12. WiMAX has a high capacity.

Using multilevel modulation schemes (e.g., 64-QAM) and channel bandwidth (currently 7 MHz, with planned evolution toward the full bandwidth

specified in the associated IEEE and ETSI standards), WiMAX systems can provide significant bandwidth to endusers.

Family of IEEE 802.16 Standards

The operation frequency bands allocated for IEEE 802.16 are between 2 and 66 GHz, which is a very wide range compared to the spectrum on which other wireless networks (e.g., WLANs, mobile cellular networks, etc.) operate. The IEEE 802.16 operation band can be further divided into two portions, one being the bandwidth between 10 to 66 GHz, which is dedicated to line-of-sight (LOS) WiMAX applications. In this band, the services are targeted for a relatively large coverage area of up to thirty miles in radius. On the other hand, the WiMAX services within a relatively small area will be given in a band between 2 and 11 GHz, in which radio wave propagation properties are better suited for NLOS applications.

As shown in Table 7, IEEE 802.16a standard services WiMAX applications in 2–11 GHz band, in which both licensed and nonlicensed radio spectra are covered. The wireless broadband access applications are offered in a point-to-point or point-to-multipoint scheme, possibly under NLOS propagation scenarios. Under the IEEE 802.16a standard, multiple receivers can be interconnected for data transmissions, and thus the total coverage areas can be extended effectively. In the IEEE 802.16b standard, the radio spectrum band in 5–6 GHz will be used. It was designed to support in particular the WiMAX services with very high requirements for QoS to provide different data applications, such as voice, data, video, and other multimedia applications (e.g., voice over IP services, etc.). On the other hand, IEEE 802.16c was proposed to provide wireless broadband data access in a relatively high band between 10 and 66 GHz, which is especially useful to deliver WiMAX services in a relatively large area. In this scheme, the LOS operation model is preferred. IEEE 802.16d (also called the IEEE 802.16-2004 standard) is an enhanced version of the IEEE 802.16a and IEEE 802.16c standards. It can operate under both 2–11 GHz and 10–66 GHz bands. The scheme offers very flexible operation modes.

All aforementioned WiMAX standards, from IEEE 802.16a to IEEE 802.16d, support only fixed or at most portable wireless broadband access; they cannot provide services to terminals with a vehicular speed mobility. Therefore, IEEE 802.16e was proposed in particular for mobility support, and its services are provided within a 2–6 GHz band. Another important feature of IEEE 802.16e is its downward compatibility to IEEE 802.16d.

We should note that there is an overlapped range in the spectral band allocation for the WiMAX applications: 2–11 GHz and 10–66 GHz. The overlapping happens in the 10–11 GHz band and will help the backward compatibility for future WiMAX applications developed for both lower and higher band operations.

Technical Aspects of IEEE 802.16

WiMAX based on the IEEE 802.16 standard has a theoretical maximum bandwidth of 75 Mbps. This bandwidth can be achieved using 64-QAM 3/4 modulation. 64-QAM

can only be utilized under optimal transmission conditions. WiMAX supports the use of a wide range of modulation algorithms to enable the most bandwidth to be realized under all conditions. WiMAX has a theoretical maximum range of thirty-one miles with a direct line of sight. However, non-line-of-sight conditions will seriously limit the potential range. In addition, some of the frequencies utilized by WiMAX are subject to interference from rain fade. The unlicensed WiMAX frequencies are subject to RF interference from competing technologies and competing WiMAX networks.

Next, we will discuss in more detail on the technical accomplishments of IEEE 802.16 standards.

MAC Layer of IEEE 802.16

The IEEE 802.16 Working Group follows the traditional IEEE 802 approach of developing multiple physical layer options supported by a common MAC layer, which was developed by Task Group 1 along with the original 10–66 GHz physical layer. Although the service requirements of the other air-interface projects differ, the original MAC layer design is flexible enough to support, with some necessary extensions, all three physical layer designs.

The IEEE 802.16 MAC layer, as shown in Figure 7, draws from the data-over-cable standard (Radio Frequency Interface Specification n.d.) that has been successfully deployed in hybrid-fiber coaxial (HFC) cable systems, which have a similar point-to-multipoint architecture. However, the MAC protocol engine uses a different design. It is a connection-oriented MAC layer architecture that is able to tunnel any protocol across the air interface with full QoS support. Asynchronous transfer mode (ATM) and packet-based convergence layers provide the interface to higher protocols. Although extensive bandwidth allocation and QoS mechanisms are provided, the details of scheduling and reservation management

are left unstandardized and provide an important mechanism for vendors to differentiate their equipment, according to some specific tailor-made requirements from the end users.

An important MAC feature in IEEE 802.16 standards is the option of granting bandwidth to a subscriber station rather than to the individual connections it supports. This provides the option of allowing a smart subscriber station to manage its bandwidth allocation among its users. This can make for more efficient allocation.

The IEEE 802.16 MAC layer is designed to be versatile and flexible. For example, it supports several multiplexing and duplexing schemes; some possibilities are described in the following subsections. In general, the point-to-multipoint architecture is implemented with a controlling base station interacting with many subscriber stations, as mentioned in the previous sections. The downlink from the base station may be channelized and sectorized, but, within a channel and sector, all subscriber stations receive the same signal and retain only messages addressed to them. The uplink from the subscriber stations is shared, with access assigned by the base station.

10–66 GHz Physical Layer of IEEE 802.16

The 10–66 GHz physical layer in IEEE 802.16 standards assumes line-of-sight propagation with no significant concern over multipath propagation. Either of two basic modes may be used. The continuous mode uses frequency division duplexing (FDD), with simultaneous uplink and downlink on separate frequencies. A continuous time-division multiplexed downstream allows a powerful concatenated coding scheme with interleaving. The burst mode allows time-division duplexing (TDD), with the uplink and downlink sharing a channel but not transmitting simultaneously. This allows dynamic reassignment of the uplink and downlink capacity. This mode also allows

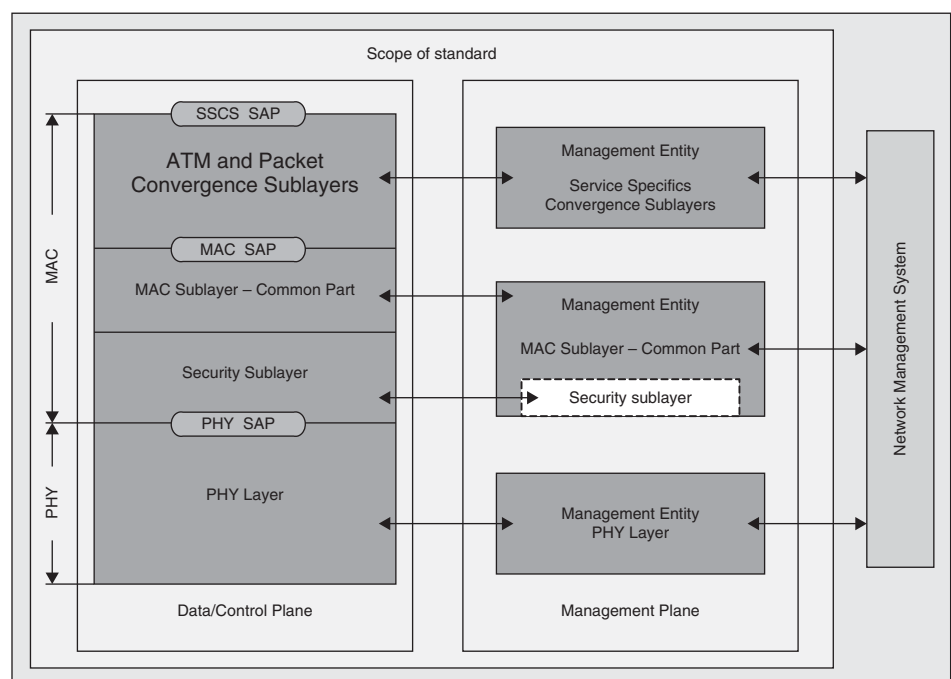

Figure 7: IEEE 802.16 reference layered model and protocol stack

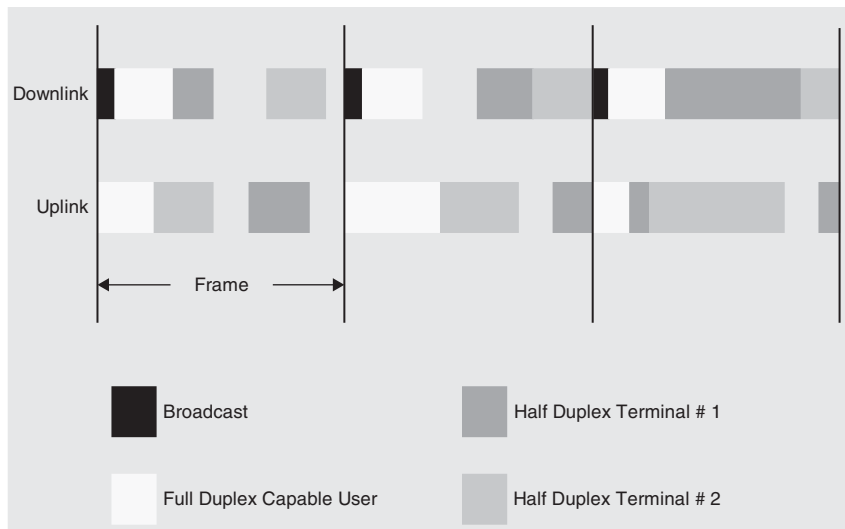

Figure 8: Example of burst FDD bandwidth allocation in IEEE 802.16 standards

burst FDD, which supports half-duplex FDD subscriber stations that do not simultaneously transmit and receive, as shown in Figure 8, and may therefore be less expensive. Both TDD and burst FDD support adaptive burst profiles in which different modulation (QPSK, 16-QAM, or 64-QAM) and coding schemes may be dynamically assigned on a burst-by-burst basis. This real-time trade-off of capacity versus robustness again offers opportunities to vendors to implement sophisticated algorithms to differentiate their approach while retaining interoperability.

The choice of continuous or burst operation mode may depend on the available channel bandwidth allocations and other regulatory issues. Because the IEEE 802.16 standards are intended for worldwide use, the channelization is left flexible, although the recommendations are included. These suggest symbols rates as high as 43.4 MBd in a 50 MHz channel, which, assuming the use of 64-QAM modulation scheme, translates to a data rate as high as 260 Mbps in that channel.

2–11 GHz Physical Layer of IEEE 802.16

Task Group 3 was responsible for developing a standard for 2–11 GHz WBA. In the United States, the primary targeted frequencies are in the multichannel multipoint distribution service bands, mostly between 2.5 and 2.7 GHz, compared to the worldwide 3.5 and 10.5 GHz that are likely allocated for the applications. Because non-line-of-sight operation is practical and because of the lower component costs, these bands are seen as good prospects for residential and small-business services. The spectrum availability is suitable to these uses. Task Group 1 considered a number of physical layer approaches and selected a baseline draft in spring 2001. At the same time, the MAC enhancements were developed.

To provide for rapid development, Task Group 4 is working under a narrow charter. It is tasked with developing a PHY layer based on the IEEE 802.11a OFDM and/or HIPERLAN/2 physical layer architecture and is developing MAC enhancements. It works closely with Task Group 3 to ensure harmony. Coordination of base stations under

independent operators in unlicensed spectrum is an important issue facing this group. One proposal is to consider an optional mesh networking architecture in addition to a point-to-multipoint topology. Some participants have proposed the MAC enhancement schemes to support the mesh networking; this is clearly a testimony to the flexibility of the IEEE 802.16 MAC. Different major IEEE 802.16 standards are compared in Table 8.

Applications of WiMAX Technology

Because of its unique features, WiMAX technology is capable of providing wireless broadband access to many important applications.

The WiMAX, as a wireless MAN technology, can connect several IEEE 802.11(WiFi) WLAN hotspots with one another and other parts of the global Internet and can provide a wireless alternative to cable and xDSL for last-mile (or first-mile) broadband access. IEEE 802.16 offers up to thirty-one miles of linear service area range and allows connectivity between users without a direct line of sight. This should not be taken to mean that users from thirty-one miles away without line of sight will have connectivity; practical limits from real-world tests seem to be around three to five miles. The technology has been claimed to provide shared data rates up to 70 Mbps, which, according to WiMAX proponents, provides enough bandwidth to simultaneously support more than sixty business users with T1-type connectivity, which is well over a thousand homes at 1Mbps xDSL-level connectivity. Real-world tests, however, show practical maximum data rates between 500 kbps and 2 Mbps, depending on conditions at a given site.

There is also some interesting potential for interoperability of WiMAX with legacy cellular networks. WiMAX antennas can share a cell tower without compromising the function of cellular arrays already in place. Companies that already lease cell sites in widespread service areas have a unique opportunity to diversify, and often already have the necessary spectrum available to them

Table 8: Comparison of Different Major IEEE 802.16 Standards

	802.16	802.16a/REVd	802.16e
Completed time	December 2001	802.16a: January 2003 802.16 REVd: Q3 2004	December 2005
Spectrum (GHz)	10–66	<11	<6
Channel condition	LOS only	NLOS	NLOS
Data rate/channelization	32–134 Mbps/28 MHz	<75 Mbps/20 MHz	<15 Mbps/5 MHz
Modulation	QPSK, 16 QAM, 64 QAM	256OFDM, OFDMA, 64 QAM, 16 QAM, QPSK, BPSK	Same as REVd
Mobility	Fixed	Fixed and portable	Mobile, regional roaming
Channel bandwidth	20, 25, 28 MHz	Selected bandwidth between 1.25 and 20 MHz, up to 16 subchannels	Same as REVd
Typical cell radius	1–3 miles	3–5 (<30 miles)	1–3 miles

(i.e., they own the licenses for radio frequencies important to increased speed and/or range of a WiMAX connection). WiMAX antennae may even be connected to an Internet backbone via either a light fiber optics cable or a directional microwave link. Some cellular companies are evaluating WiMax as a means of increasing bandwidth for a variety of data-intensive applications. In line with these possible applications is the technology's ability to serve as a very high bandwidth "backhaul" for Internet or cellular phone traffic from remote areas to a backbone. Although the cost-effectiveness of WiMAX in a remote application will be higher, it is definitely not limited to such applications, and may in fact be an answer to expensive urban deployments of T1 backhauls as well. Given developing countries' (such as those in Africa) limited wired infrastructure, the costs to install a WiMax station in conjunction with an existing cellular tower or even as a solitary hub will be diminutive compared to developing a wired solution. The wide, flat expanses and low population density of such an area lends itself well to WiMAX and its current diametrical range of thirty miles. For countries that have skipped wired infrastructure because of of inhibitive costs and unsympathetic geography, WiMAX can enhance wireless infrastructure in an inexpensive, decentralized, deployment-friendly, and effective manner.

WiMAX technology provides an important means to establish emergency telecommunication links to the outside world, such as natural disaster rescue missions, where the wired or cellular network infrastructure may be totally destroyed by earthquake, tsunami, hurricane, and so forth. The usefulness of WiMAX in disaster relief operations is due mainly to its operation readiness and deployment flexibility. You need only to mount a WiMAX base station on top of a master from which a secure connection (also via microwave links) with outside networks is available, and then you can establish the voice, data, and video communications. Some companies have started to design WiMAX products for emergency telecommunication applications.

A good example of the effectiveness of WiMAX was the aftermath of the devastating Hurricane Katrina. The FCC allowed an isolated temporary shelter in rural Louisiana to use the still-experimental technology WiMAX as a powerful, high-speed wireless link to the nearest functioning Internet connection point, fifteen miles away. WiMAX worked flawlessly and now discussions are under way to make wireless access a big part of New Orleans' reconstructed communications infrastructure.

Because of its deployment agility, military operations are yet another possible application for WiMAX technology, which can be deployed and torn down very quickly for battlefield telecommunication and commanding applications. WiMAX-based ad hoc or mesh wireless networks can provide a vital communication solution for future military operations.

Public safety services and private networks are another potential application of WiMAX technology. Support for nomadic services and the ability to provide ubiquitous coverage in a metropolitan area provide a tool for law enforcement, fire protection, and other public safety organizations, enabling them to maintain critical communications under a variety of adverse conditions. Private networks for industrial complexes, universities, and other campus type environments also represent a potential business opportunity for WiMAX.

Another interesting application of WiMAX under consideration is gaming. Sony and Microsoft are closely considering the addition of WiMax as a feature in their next generation of game consoles. This will allow gamers to create ad hoc networks with other players. This may prove to be one of the "killer applications" driving WiMax adoption: WiFi-like functionality with vastly improved range, greatly reduced network latency, and the capability to create ad hoc mesh networks.

WiMAX technology can also provide an important means for offshore communications. Oil and gas producers can use WiMAX equipment to provide communication

links from land-based facilities to oil rigs and platforms, to support remote operations, security, and basic communications. Remote operations include remote troubleshooting of complex equipment problems, site monitoring, and database access. For example, video clips of malfunctioning components or subassemblies can be transmitted to a land-based team of experts for analysis. Security includes alarm monitoring and video surveillance. Basic communications includes voice telephony, e-mail, Internet access, and video conferencing. WiMAX networks are quickly and easily deployed. The network can be set up or redeployed in a matter of hours, if not minutes, even when oil rigs and platforms are moved to other locations. Wired solutions are not appropriate for this scenario because the facilities are offshore, and because oil rigs are temporarily located and moved regularly within the oil or gas field. In the event of having to temporarily abandon an offshore facility, communications for monitoring the status of the asset can continue to be maintained if using battery-backed WiMAX terminals.

Government agencies, large enterprises, industrial campuses, transportation hubs, universities, and colleges, can use WiMAX networks to connect multiple locations, sites, and offices within their campus. Campus communication systems require high data capacity, low latency, a large coverage footprint, and high security: like other usage scenarios, campus networks carry a mixture of voice, data, and video, which the WiMAX QoS helps prioritize and optimize. It takes less time and fewer resources to interconnect a campus through a WiMAX network, because excavation and external construction are not required. Some campuses have been in place for a long time, and digging trenches for cable may not be permitted. In such cases, WiMAX solutions may be one of the most cost-effective ways to interconnect campus buildings. Even if wired installations are permitted, the lead time to deploy a wired solution is much longer than the lead time to deploy a WiMAX solution, without offering any accompanying benefits.

Obviously, WiMAX technology can also be a vital solution to provide rural connectivity. Service providers use WiMAX networks to deliver service to underserved markets in rural areas and the suburban outskirts of cities. The delivery of rural connectivity is critical in many developing countries and underserved areas of developed countries, where little or no infrastructure is available. Rural connectivity delivers much-needed voice telephony and Internet service. Because the WiMAX solution provides extended coverage, it is a much more cost-effective solution than wired technology in areas with lower population densities. WiMAX solutions can be deployed quickly, providing communication links to these underserved areas, thereby offering a more secure environment, and helping to improve their local economies.

Released WiMAX Services/Products

Many WiMAX products have been announced since the second quarter of 2005. For example, major cities such as Los Angeles, New York, Chicago, Boston, Providence (Rhode Island), and San Francisco/Oakland will be served by TowerStream, as of 2005. TowerStream claims to

offer a complete Internet and VoIP phone solution, which charges a very reasonable price for T1 Internet Access plus VoIP phone lines. TowerStream uses the latest fixed-wireless technology that is the basis of WiMAX.

On the other hand, Seattle is served by Sprint and Speakeasy net, which can service T1 Internet access and VoIP lines. It can also offer a private WAN service that delivers private point-to-multipoint connections for the small to medium-sized business based on fixed WiMAX technology.

In China, Dalian and Chengdu are implementing pre-WiMAX networks that will be upgradeable when certification testing begins. Current Towerstream, Speakeasy, and other deployments are of proprietary systems that include Airspan Networks, Aperto, Alvarion VL OFDM, and Dragonwave. Trial deployments have been mostly outside of the United States because of limited spectrum availability. Sprint has announced that it will begin trials of precertified WiMAX systems. TowerStream will also introduce WiMAX systems to follow their highly successful pre-WiMAX network servicing businesses, educational facilities, and government entities.

At the July 2005 WiMAX Forum meeting in Vancouver, British Columbia, Canada, WiMAX systems began certification testing. Disney took part in the proof of concept (POC) display, which showed real simultaneous multimedia capabilities possible through the WiMAX technology.

In addition to the aforementioned urban area rollouts, WiMAX is like WiFi in that you can "roll your own." Several vendors already had some form of products in 2004, usually in a pre-standards-compliance stage so that multivendor interoperability within a single network segment could not be reasonably expected. Several companies have been planning rollouts of compliant chipsets in FPGAs in 2005 and ASICs the following year, which will shrink the digital electronics suitable for PCMCIA and MiniPCI type of form factors. Intel is expected to be a major driver toward price reduction. Taken at face value, Intel claims to be able to drive the price per user to zero over the next three to four years, as a result of embedding WiMAX function into the system processors and board architectures for notebook PCs, PDAs, and other devices. Of course, the price will not be zero exactly because premium features drive acceptance of premium "Intel Inside"-driven designs. But as a competitive positioning strategy, the ability to embed multimode WiMAX/WiFi/cellular into consumer and IT products should create a compelling argument for WiMAX's acceptance.

WiBro Technology

When talking about WiMAX services, we have to take a look at WiBro technology, which was a wireless broadband access standard created independently by the South Korean government, showing that Korea will aim for WBA even without the blessing of the international community. However, the development of the WiBro technology proceeded under the shadow of the IEEE 802.16 WiMAX standard with regard to its technical specifications and architecture for both the physical and upper layers.

The WiBro supports mobile terminals up to 120 km/h, and its base station can cover an area of 1–5 km in radius.

Table 9: The Comparison of WiBro Technology with Other Wireless Networking Technologies

	WiBro	TD-CDMA	HSDPA	EV-DO	WLAN
Peak data rate	DL: 18.4 Mbps UL: 6.1 Mbps	DL: 3.1 Mbps UL: 900 Kbps	DL: 14 Mbps UL: 2 Mbps	DL: 3.1 Mbps UL: 1.2 Mbps	802.11b: 11 Mbps 802.11a/g: 54 Mbps
Bandwidth	9 MHz	5 MHz(10 MHz)	5 MHz	1.25 MHz	20 MHz
Air link	OFDMA	TDMA, CDMA	TDMA, CDMA	CDMA	CSMA/CA
Duplex	TDD	TDD	FDD	FDD	TDD
Mobility	Mid	High	High	High	Low
Coverage	Mid	Mid	Large	Large	Small
Standard	TTA & 802.16e	3GPP	3GPP	3GPP2	802.11

The Korean government has allocated 100 MHz bandwidth at 2.3 GHz band in particular for WiBro services. The Phase 1 standardization for WiBro technology was finalized in June 2004, and WiBro technology was put into trial service in 2005 at the Pusan APEC meeting, which showed its impressive performance to all delegates in attendance. Another importance chance for Korean to demonstrate their WiBro technology is the Winter Olympic Games to be held in Turin, Italy, February 2006. Samsung will provide the WiBro-based wireless broadband access technology to the organizer of the Turin 2006 Winter Olympic Games. The next-generation WiBro technology will provide a downlink data rate up to 20 Mbps and uplink data rate up to 6 Mbps, which will be 1.4 to 3 times faster than what HSDPA (an enhanced W-CDMA) can do. Therefore, the kind of impact WiBro technology exerts on the WWANs still needs to be watched closely. The comparison between WiBro and other different wireless networking technologies is shown in Table 9.

Therefore, we have to say that, until now, perhaps the most telling deployments for WiMAX will be for the WiBro mobile derivative: WiBro has the South Korean government's support with the requirement for each carrier to spend over one billion U.S. dollars for deployments. The Koreans sought to develop WiBro as a regional and potentially international alternative to 3.5-4G systems. But given the lack of self-developed momentum as a standard, WiBro has joined WiMAX and agreed to harmonize with the similar OFDMA-based 802.16e version of the standard. What makes WiBro rollout, which will start in April of 2006, a good test case for the overall WiMAX effort, is that it is mobile and well thought-out for delivery of WBA services, and the fact that the deployment is taking place in a highly sophisticated, broadband-saturated market. WiBro will go up against 3G and very high-bandwidth wire line services rather than as gap filler or rural underserved market deployments. WiBro will be in direct competition with 3G and high-bandwidth wired services, which pose tough competition.

In a very interesting move, WiMAX heavyweight supporter, Intel, and WiBro technology proponent, LG Electronics, announced in November 2005 that they would work together to speed up the harmonization of worldwide WMAN technologies, including WiMAX and WiBro technologies. Intel will support the merging of WiMAX

**Figure 9:** Samsung SPH-M8000 WiBro smart phone

and WiBro standards to reduce the redundant investment on the similar WMAN technologies throughout the world. This move, according to many is positive for all parties as it will eventually benefit the end users and equipment vendors as well. At the moment, the Korean government is about to issue three WiBro licenses. Many people believe that three Korean companies, KT, SK Telecom, and Hanaro Telecom, will most likely be the winners.

Samsung Electronics recently demonstrated its first WiBro smart phone, SPH-M8000 (see Figure 9), at the Second Communication and Broadcasting Convergence Exhibition & Conference. This model of a WiBro phone uses a slide-up front cover design with a QWERTY full-functional keyboard under the front cover. It operates on the platform of Windows Mobile 2003 Second Edition for Pocket PC Phone with Intel PXA272 CPU, which can run up to a 520 MHz clock. Its screen uses 2.8 inch QVGA (240 × 320) TFT touch panel with 260,000 colors. The SPH-M8000 is equipped with two cameras, the front one using 300,000 resolution and the back one using 3 million resolution. It also supports Bluetooth v1.1 for earphone and other short-range communications. The weight of SPH-M8000 is only 184 g, which is very light to carry around.

WIRELESS WIDE AREA NETWORKS (WWANs)

Wireless wide area networks encompass a fairly large group of wireless technology, or mobile cellular technologies, which have experienced three generations until now. The first generation (1G), including AMPS, NMT, TACS, and so forth, was based on analog technology and very large cell size. The average capacity of the 1G WWAN was very low and international roaming was not possible. The 2G WWAN technology was based on digital technology; examples include GSM, IS-95, JDC, and so on. Similar to the 1G cellular systems, 2G WWANs were still voice centric, and they had limited capability to support slow data services. The 3G WWANs include CDMA2000, W-CDMA, and TD-SCDMA standards, proposed respectively by the United States, Europe/Japan, and China, to respond to the call from the ITU for IMT-2000 global mobile telecommunication initiatives. Today, 3G cellular networks have been deployed in many countries throughout the world.

Because our objective here is to discuss WBA, we will not discuss any of the details of the 3G cellular standards, although they also belong to WBA technology in a broad sense. However, we will need to know the difference between the major 3G standards and WiMAX technology in this section so that we can understand more about the possible future developmental trends of the two technologies. A recent move made by WiMAX is the standardization of IEEE 802.16e, which is able to support vehicular-speed mobility and regional roaming (handoffs); thus, the boundary between the mobile cellular and WiMAX technologies becomes very blurred. This necessitates a clearer definition of the roles WiMAX plays in the midst of cellular mobile system evolution from 3G to B3G. The question now is whether WiMAX will be a gap filler of different wireless services (as claimed now by Intel and many other WiMAX proponents), including mobile cellular and WLANs, or will it be a strong competitor for the future mobile communication market with 3G and B3G cellular technologies? This is not an easy question to answer at the moment.

If we look at the air-link technologies adopted by 3G WWANs and WiMAX systems, we find that the 3G is dominated by CDMA multiple access technology without exception: all 3G standards including CDMA2000, W-CDMA, TD-SCDMA, and so forth use CDMA for their air-link technology. On the other hand, WiMAX promotes strongly OFDMA technology as its primary multiple-access physical layer architecture. There have been many serious debates in symposia and conferences around the world about which form of multiple-access technology should be selected as B3G's core air-link design: CDMA or OFDMA? It is, again, a difficult question to answer. At the moment, it seems that the OFDMA has the upper hand, and more people tend to support the use of OFDMA, than CDMA, which is now considered a legacy technology that should be replaced by something new (e.g., OFDMA). Therefore, the comparison of the 3G WWANs versus WiMAX seems to be equal to the comparison of CDMA versus OFDMA. For this reason, we offer some discussions on the issue as follows.

Multipath Mitigation in 3G and WiMAX

Multipath interference occurs when multiple reflected signals arrive at a same wireless receiver. These signals may have been reflected off of buildings, walls, trees, hills, or other solid objects. When the mobile user is indoors (and the base station is located outside), there is no line-of-sight signal at all. Because each of the signals is reflected from different objects, each has traveled a different distance, causing some signals to arrive earlier than others. This results in the signals arriving at random phase offsets of one another. The signals then experience fading through destructive (and constructive) interference when the signals become superimposed on one another. This interference is often referred to as Intersymbol interference (ISI). The amount of fading depends on the delay spread of the signal as well as the power level of each signal (some multipath returns may have weaker signals due to attenuation, possibly caused by an object such as a tree).

Technologies using CDMA (e.g., 802.11b and 3G) and other wideband technologies are very susceptible to multipath fading, because the delay time can easily exceed the symbol duration, which causes the symbols to completely overlap (ISI). The use of several parallel subcarriers in OFDMA enables much longer symbol duration, which makes the signal more robust to multipath time dispersion. For example, if we want to send information at a rate of 1000 bps, we could do this serially where each bit would take 1/1000th of a second. Any delays longer than 1/1000th of a second would overlap the next bit. On the other hand, by sending 1000 bits in 1000 parallel streams, each bit would take one second to transmit and a 1/1000th second delay would only overlap by 1/1000th of the transmission interval for any given bit, basically eliminating any interference. By adding a small guard time, the ISI can effectively be mitigated in OFDMA.

Multipath fading affects certain frequencies of a transmission and can result in deep fading at certain frequencies, resulting in frequency selective fading. One reason this occurs is because of the wideband nature of the signals. When a signal is reflected off of a surface, different frequencies reflect in different ways. In Figure 10, both CDMA (left) and OFDMA (right) experience selective fading near the center of the band. With optimal channel coding and interleaving, these errors can be corrected (the coded BER does not increase at all). CDMA tries to overcome this by spreading the signal out and then equalizing the whole signal (the coded BER increases proportionally to the increase in the raw BER). OFDMA is therefore more resilient to frequency selective fading than CDMA.

Adaptive Modulation and Coding in 3G and WiMAX

Both W-CDMA (HSDPA) and OFDMA utilize QPSK and QAM. For W-CDMA, adaptive modulation and coding (AMC) is only used on the downlink (HSDPA), because the uplink still relies on W-CDMA 3rd-Generation Partnership Project (3GPP) release 99, which uses QPSK but not QAM. Modulation and coding rates can be changed to achieve higher throughput, but higher-order modulation will require better channel conditions (i.e., signal-to-noise

Figure 10: Comparison of CDMA and OFDMA under frequency selective fading channel, where the dotted area represents the transmitted spectrum and the solid area is the receiver input

Table 10: System-Level Performance Results for FTP Traffic with Maximum Throughput Scheduling

	OFDMA	W-CDMA(MMSE)	W-CDMA(RAKE)
Users per sector	40	40	40
Average OTA throughput (Mbps)	4.45	3.83	3.03
Average packet call throughput (kbps)	1802	1170	490
Average residual BLER	0.002	0.002	0.000
Average packet delay (s)	2.33	3.56	8.54

ratio). WiMAX uses higher-order modulations like QAM 64 to the areas closer to the base station, whereas lower-order modulations like QPSK are used to extend the range of the base station.

Performance results, conducted for one of the 3GPP Working Groups (R1-040571 2004), showed that although OFDMA is able to achieve the maximum throughput of 9.6 Mbps (16-QAM), W-CDMA (HSDPA) does not exceed 3 Mbps. From these results, it appears that an even higher discrepancy may be found when utilizing higher modulation and code rates to yield even higher throughput for OFDMA. Table 10 shows some system-level performance results comparing WiMAX and W-CDMA (HSDPA) (3GPP 2004). Even with more advanced receivers (MMSE), OFDMA is found to perform better in this environment. Furthermore, these results were obtained using OFDMA up to 16-QAM. Using more advanced OFDMA and modulation techniques (such as those included in 802.16e), the gap would likely widen. WiMAX (802.16e) in fact supports a higher-order modulation of 64-QAM (optional 256-QAM). It is important to note that although both of these technologies offer higher throughput, it appears that OFDMA may provide a greater range of higher throughput when compared to HSDPA (where the highest speeds, using 16-QAM, may only be provided within hot-spot size coverage). It should also be noted that, although AMC can be utilized in both the downlink and uplink for WiMAX, AMC has only been defined for the downlink portion of W-CDMA (HSDPA).

AMC in a multipath environment may offer OFDMA further advantages because the flexibility to change the modulation for specific subchannels allows WiMAX to be

optimized at the frequency level. Another alternative would be to assign those subchannels to a different user who may have better channel conditions for that particular subchannel. This could allow users to concentrate transmit power on specific subchannels, resulting in improvements to the uplink budget and greater range. This technique is known as space division multiple access (SDMA). Figure 11 shows how subchannels could be chosen depending on the received signal strength. The subchannels on which the user is experiencing significant fading are avoided, and power is concentrated on channels with better channel conditions. With OFDMA, the client device could choose subchannels based on geographical locations with the potential of eliminating the impact of deep fades. CDMA-based technologies utilize the same frequency band regardless of where the user is. Of course, the assistance from smart antenna can give a CDMA a similar capability, but at a high implementation cost.

Spectral Efficiency of 3G and WiMAX

Spectral efficiency is another serious concern to an operator because of the limited spectrum availability and the cost of a spectrum license. It is also important to consider frequency reuse to understand deployment of multiple cells. OFDMA typically requires a frequency reuse factor of one to three, implying that the available spectrum must be split up into a three-cell formation. For example, if a carrier has 5 MHz of available spectrum, it needs to divide it into three channels of 1.75 MHz each, so that adjacent cells utilize different frequencies to avoid interference. For WiMAX, this results in a maximum of

Figure 11: OFDMA avoids subchannels with deep fade; the signals on the top indicate the received signal strength, and the bottom part of the figure indicates which subcarriers are then chosen for each signal. Source: U.S. Census Bureau, 2004

approximately 6 Mbps per cell compared to 14.4 Mbps achievable by HSDPA. However, although the maximal throughput may be lower for WiMAX, it must be remembered that the 14.4 Mbps achievable by HSDPA would be very limited in coverage. WiMAX also supports larger channel sizes up to 20 MHz. To overcome this limitation, OFDMA systems can maintain a frequency reuse near one if there are location-sensitive transmissions near the edge of the cell that use a subset of the carriers, and/or if using advanced antenna systems (AAS), although AAS may be too expensive.

In CDMA-based 3G WWANs, the coverage of the cell expands and shrinks depending on the number of users. This is known as *cell breathing* and occurs because, with CDMA, users transmit at the same time (and are identified by their unique codes). The interference is averaged among the other users so that, as users are added to the cell, the coverage shrinks, and as users leave the cell, the coverage expands. A user downloading data can significantly reduce the coverage and force voice users to “soft” handoff to another cell. Such an increase in handoff rates would require that more cells be added to ensure coverage and eliminate any dead spots. This problem could be worsened with the deployment of HSDPA as a result of more bursty data and higher data rates. Another possible solution would be to deploy HSDPA on a separate 5 MHz channel.

HSDPA aggregates up to fifteen shared codes for highest capacity. Each user of the HSDPA channel requires a unique code for control access to the data channel. This limitation in code availability could lead to blocked voice calls. Because of this limitation and client complexity, most clients will initially be limited to five codes. Furthermore, because each user will require at least one code or carrier set allocated to him or her this can have a great impact on the number of users supported by each system. CDMA systems must also provide one code for each voice call, which implies that, in order to support a broadband data pipe, service providers will need to deploy HSDPA on a separate 5 MHz channel.

Before ending this section, we would like to look back at the issue raised at the beginning of this section. CDMA technology was “invented” by Qualcomm Inc., which, without

a doubt, was the first company to introduce the CDMA into commercial (or civilian) applications in a large scale, making interim standard 95 (IS-95) for cellular mobile systems one of the major 2G technologies. It should also be noted that Qualcomm is still holding the majority of CDMA-related patents or IPRs, which have given the company a great deal of benefit in terms of the loyalty returns, license fees, and so on, making the company one of a very few perpetual gainers in the U.S. stock market. The sky-rocketed share price of the company today is proof of this. Therefore, Qualcomm obviously enjoys the current status quo of dominance of CDMA technology in the global 3G cellular market. Nobody knows what Qualcomm will do if B3G abandons CDMA and use another multiple-access technology, such as OFDMA. As mentioned earlier, Qualcomm recently secured the acquisition of Flarion, a small company that developed a coded OFDMA scheme to potentially replace CDMA as a prime multiple-access technology for B3G wireless, including WiMAX. The reposturing of their systems and OFDM patent portfolios as being central to OFDMA-based IEEE 802.16e developments has broadened the level of interest in the emerging field of OFDMA wireless. Some questioned the motivation of Qualcomm’s move: is this an attempt to stall adoption of WiMAX? Or is this recognition by Qualcomm that OFDMA will likely become a predominant core multiple-access technology for 4G and beyond wireless systems? The answer to these questions will not be known for some time.

WIRELESS REGIONAL AREA NETWORKS

This section covers a new IEEE 802 standard, or IEEE 802.22, which is targeted at VHF/UHF analog TV bands to be released from U.S. TV companies that will upgrade their traditional analog TV to digital TV broadcasting services. The wireless data networks based on the IEEE 802.22 standard (2004) will be called wireless regional area networks or simply Wi-TV technology.

Initially, the FCC was looking at means by which the 6 MHz wide licensed spectrum in the UHF band (FCC 2004) currently assigned to TV broadcasters, can be reused in secondary markets as a path to last-mile data access

(for this reason, we can also refer to WRANs as a useful means of providing WBA services). This proposal would set power levels up to 8 dB higher than those currently allowed in those bands, thereby greatly increasing range and coverage area. In addition, the propagation characteristics at the lower UHF frequencies are particularly attractive, offering the possibility of longer distance, lower power, and fewer base stations.

It is interesting to note that many technologies could use this TV spectrum, although the WiMAX community is keen to claim it for its own. In March 2004, when the IEEE 802.22 group was set up, the powerful IEEE 802.16 Working Group was angered when its proposal that the cognitive radio work should be kept under its auspices, rather than in a separate group, was defeated. However, this has not halted its supporters, led by Intel, in their quest to turn the IEEE 802.22 efforts to their advantage.

The story behind the conflict between IEEE 802.16 and IEEE 802.22 groups highlights the importance of cognitive radio technology and its applications in either WMANs or WRANs operating in underused VHF/UHF TV bands. The cognitive radio technology used for IEEE 802.22 will act as its core to scan the bands, select those unoccupied for its communications purpose, and stop immediately when it detects the signals sent from incumbent users.

The IEEE 802.22 Working Group insisted when the group began work that Wi-TV would work with existing IEEE 802 architectures, serving as a regional area network complementing both the WiFi WLANs and the WiMAX WMANs. The IEEE 802.22 group also pointed out that WiMAX is not suitable for TV spectrum because it does not include cognitive radio functions. On the other hand, the IEEE 802.16 group denounced that claim, noting that WiMAX does in fact have a provision for cognitive radios (which will be included in its new amendment, standard IEEE 802.16h) to avoid interference with other WiMAX devices at higher frequencies, and that it could easily be adapted for UHF frequencies.

In December 2004, the IEEE 802.22 group accused the 802.16 group of overstepping its scope and developing its cognitive radios for “coexistence with primary users,” not just WiMAX users, and asked the WiMAX committee to reaffirm the limits of its scope. The WiMAX group declined and received support from another IEEE task group, 802.19, which saw no reason why both groups could not work on the problem separately. The fight is still going on about which group will be allowed to use the VHF/UHF bands for wireless broadband access, even with the help of cognitive radio technology. At the time of the writing of this chapter, the 802.22 group appears to have been given permission to move forward, while the 802.16 group has to stay on its original 2–66 GHz bands.

CONCLUSION

This chapter begins with the definition of wireless broadband access technology, and then, by following its broad definition, reviews almost all possible candidates for the WBA applications: WLANs, WPANs, WWANs, WRANs, and, of course, WMANs. The chapter can serve as an information source for wireless data networking in general, although we focus on WMAN, or simply WiMAX.

This chapter is written in a way that is suitable for everyone, from a communications engineer with background knowledge on wireless communications and networks, to a student who is just beginning his or her third year of study in an undergraduate program. The introduction of different wireless networking technologies proceeds in a very descriptive way, with little mathematics. Many illustrations have been used to give vivid pictures of the complex concepts behind each wireless technology. Therefore, we hope that this chapter will be found useful to people who are working to achieve their goals in related professions.

ACKNOWLEDGMENT

We would like to take this unique opportunity to express our sincere thanks to all of the people who helped us in the entire course of preparation of the chapter. Specifically, we want to thank Professor Hossein Bidgoli for his kind invitation to make the writing of this chapter possible. At the same time, both Hsiao-Hwa Chen and Mohsen Guizani would like also to thank many of their students for their assistance during this project as well as their families for their patience and encouragement.

GLOSSARY

- ALOHA NET:** A packet radio data network developed at the University of Hawaii in the early 1970s to provide wireless data access to different campuses in the university.
- IEEE 802.11:** A series of standards made by IEEE to specify the operation of wireless local area networks.
- IEEE 802.11a:** A WLAN standard that operates in the 5 GHz band and offers a data transmission rate up to 54 Mbps.
- IEEE 802.11b:** A WLAN standard that operates in the 2.4 GHz band and offers a data transmission rate up to 11 Mbps.
- IEEE 802.11g:** A WLAN standard that operates in the 2.4 GHz band and offers a data transmission rate up to 54 Mbps. IEEE 802.11g is backward compatible with IEEE 802.11b.
- IEEE 802.11p:** A new wireless networking standard that is dedicated to vehicular wireless access. It is also called *dedicated short-range communications* or simply *WAVE technology*.
- IEEE 802.15:** A series of standards for wireless personal area networks (WPANs).
- IEEE 802.15.1:** A WPAN standard based on Bluetooth technology.
- IEEE 802.15.3a:** A WPAN standard based on ultra-wideband (UWB) technology.
- IEEE 802.16:** A series of standards for wireless metropolitan area networks (WMANs).
- IEEE 802.16e:** Specifies the standard for WMANs operating in the 2–6 GHz band. It can also support vehicular mobility.
- IEEE 802.22:** Specifies a new wireless networking standard targeted at VHF/UHF analog TV bands to be released from those U.S. TV companies that will upgrade their traditional analog TV to digital TV broadcasting services.

WBA: Wireless broadband access.

WiBro: A technology to support wireless metropolitan area networks developed by the Korean government. It can support mobile terminals up to 120 km/h and its base station can cover an area of approximately 1–5 km in radius. It will be made compatible with WiMAX eventually, although currently it is not.

WiMAX: Worldwide Interoperability for Microwave Access, a certification mark for products that pass conformity and interoperability tests for the IEEE 802.16 standards.

WLAN: Wireless local area network.

WMAN: Wireless metropolitan area network.

WPAN: Wireless personal area network.

WRAN: Wireless regional area network.

INTRODUCTION

The fourth generation (4G) wireless communication systems will include a number of different complementary access technologies rather than a single technology, with the ultimate goal of providing omnipresent connectivity, ranging from high-mobility cellular systems to fixed and low-mobility indoor environments. Today's RF based networks may be able to support one or perhaps two high-capacity users per cell, which is highly wasteful with cell sizes of ~100 meters accommodating ten's of users. Multiple high-capacity users could only be serviced by deploying a similar number of systems, all within the same locale. This would create a situation where the multiple cells almost completely overlap, which then raises concerns with regards to interference, carrier re-use, etc. In contrast, IR could deliver the necessary capacity to each user through multiple user-sized cells, and because of the intrinsically abrupt boundary of these cells, interference would be negligible and carrier re-use would not be an issue. Indeed, IR (or OW) is a future proofed solution because additional capacity far beyond the capabilities of radio could be delivered to users as their needs increase with time. Figure 1 shows the mobility of RF and OW systems for a range of bit rates. Perhaps the largest installed short-range stationary wireless communications links are optical, rather than RF. It is argued that IR has a part to play in the wider 4G vision. In large open environments such as railway station, exhibition halls, etc., where individual users require 100 Mbps or more, IR with tracking capabilities could be the most sensible solution because of its improved wavelength re-use within the same location, security, and high data rates.

First proposed as a medium for short-range wireless communication more than two decades ago, IR wireless offers a number of advantages over its RF counterpart, such as abundance of unregulated bandwidth (200 THz

in the 700–1500 nm range), no multipath fading when intensity modulation and direct detection is used, high security connectivity, higher capacity per unit volume (bps/m³) due to neighboring cells sharing the same frequency, cost effectiveness at rates near 100 Mbps, small cell size and minimal absorption effects at 800–890 nm and 1550 nm wavelengths. The comparison between RF and IR for indoor wireless communications is shown in Table 1. Optical wireless LAN has been used in large scale in a number of applications such as telemedicine, laptops, PDAs, museums, etc (Kahn and Barry 1997). According to the IEEE 802.11 specifications, the OW physical layer can support data rate up to 2 Mbps with a potential to migration to higher data rates (IEEE Standard 802.11 1997). The operating wavelength is between 850 nm and 950 nm and the link span could be as long as 10–12 m. The Infrared Data Association (IrDA) has standardised low cost and short range (1–8 m) infrared data links supporting data rates ranging from 2.5 kbps to 16 Mbps (for a short range line-of-sight) at wavelength between 850 nm and 900 nm (IrDA 2006). To an extent, RF and IR may be viewed as complementary rather than competitive media. For example, if a wireless LAN is required to cover a large area in which users can roam freely and remain connected to the network at all times, then RF is the only cost-effective medium that can achieve this. If, however, a wireless LAN is required to cover a more modest area but deliver advanced bandwidth-hungry multimedia network services such as video conferencing and video on demand, then IR is the only medium that truly has the bandwidth available to deliver this.

This chapter provides a general introduction to the indoor optical wireless links, discussing their unique properties and the constraints imposed on the system. Also discussed are the various link configurations and their advantages and disadvantages, the channel characteristics, ambient light interference, and modulation schemes.

Figure 1: Mobility of RF and optical wireless (IR) systems versus bit rate

Table 1: Properties of Radio and Infrared Wireless

Property	Radio	Infrared	Implication for Infrared
Bandwidth regulated	Yes	No	Approval not required World-wide compatibility
Passes through walls	Yes	No	Inherently secure Carrier reuse in adjacent rooms
Multipath fading	Yes	No	Simple link design
Multipath dispersion	Yes	Yes	Problematic at high data rates
Path loss	High	High	
Dominant noise	Other users	Background light	Short range
Average power is proportional to	$\int f(t) ^2 dt$, $f(t)$ is the input signal	$\int f(t) dt$	High peak-average ratio

PROPERTIES OF INDOOR OPTICAL WIRELESS LINKS

For low-cost IR wireless communications, intensity modulation with direct detection (IM/DD) is the only feasible method of communication (Barry 1994). In this mode of operation, the intensity or power of the optical source $x(t)$ is directly modulated by varying the drive current. At the receiver, a photodetector is used to generate a photocurrent $y(t)$, which is proportional to the instantaneous optical power incident upon it. As with RF systems, indoor OW links are also subject to multipath propagation, which is most pronounced in links using non-directional transmitters and receivers. Multipath propagation causes the received electric field to undergo severe amplitude fades on the scale of a wavelength, and consequently, a detector smaller than one wavelength would experience multipath fading. However, in IR the total photocurrent generated is proportional to the integral of the optical power over the entire photodetector surface, which is typically millions of square wavelengths, thus providing

an inherent spatial diversity to prevent multipath fading (Barry 1994). However, multipath propagation does lead to dispersion, thus resulting in pulse spreading. Here the channel is modelled as a linear baseband channel with an impulse response $h(t)$ as shown in Figure 2, where R is the photodetector responsivity.

Optical wireless transceivers usually operate in environments containing an intense amount of ambient light emanating from both natural (solar) and artificial sources (incandescent and fluorescent). The average combined power of this background radiation generates a DC photocurrent I_B in the photodetector, giving rise to shot noise $n(t)$, which has a single-sided power spectral density N_o , given as (Moreira et al. 1995):

$$N_o = 2qI_B, \quad (1)$$

where q is the electron charge. Even when optical filtering is used to reject out of band light sources, the received signal power is much lower than the power from ambient light sources, typically 25 dB lower (Barry 1994).

Figure 2: A typical IM/DD optical wireless system block showing transmitter, channel, receiver

Consequently, I_B is much larger than the maximum photocurrent generated by the signal, and hence, the shot noise may be regarded as white, Gaussian, and independent of the received signal (Lee and Messerschmitt 1994). In the presence of intense ambient light, which is usually the case, shot noise is the dominant noise source in a typical diffuse receiver (Barry 1994). Note that if little or no ambient light is present, the dominant noise source is receiver preamplifier noise, which is also signal independent and Gaussian. Additionally, artificial ambient light sources also generate a periodic interference signal, which must be added to $n(t)$. The equivalent base-band model of an optical wireless link (see Figure 2), can be summarised by (Kahn and Barry 1997):

$$y(t) = Rx(t) \otimes h(t) = n(t), \quad (2)$$

where the symbol “ \otimes ” denotes convolution. $x(t)$ defined in terms of information data sequence $\{s_n\}$ and symbol time T_s is given as:

$$x(t) = \sum f_{s_n}(t - nT_s). \quad (3)$$

While (2) is simply a linear filter channel with additive noise, IR systems differ from conventional electrical or RF systems because $x(t)$ represents power rather than amplitude. This places two constraints on the transmitted signal. Firstly, $x(t) \geq 0$, and secondly, eye safety requirements limit the maximum optical transmit power which may be employed. Generally, it is the average power P_t requirement which is the most restrictive and hence, the average value of $x(t)$ must not exceed a specified value of P_t defined as (Barry 1994):

$$P_t \geq \lim_{T \rightarrow \infty} \frac{1}{2T} \int_{-T}^T x(t) dt. \quad (4)$$

This is in contrast to the time-averaged value of $|x(t)|^2$, which is the case on conventional channels when $x(t)$ represents amplitude. The average received optical power is given by $P_r = H(0)P_t$, where $H(0) = \int_{-\infty}^{\infty} h(t) dt$ is the channel DC gain.

LINK CONFIGURATION

Indoor optical wireless links may be configured in a variety of ways to support a multitude of applications. Street et al. (1997) grouped these into four generic system configurations: directed LOS, non-directed LOS, diffuse, and tracked, as illustrated in Figure 3.

Figure 3: Link configurations: (a) directed LOS, (b) non-directed LOS, (c) diffuse, and (d) tracked

Directed LOS

Direct LOS as shown in Figure 3(a), offers excellent transmission capacity up to a few Gbps and high power efficiency by using narrow beam transmitters and narrow field of view (FOV) receivers. The use of narrow FOV receivers allows optical concentrators to be employed along with thin film optical filters, because the angular dependence of the filter response does not pose a problem. Furthermore, directed LOS systems do not suffer from multipath propagation, and ambient background light is largely rejected. Thus, the potential data rate is limited only by the available power budget rather than multipath dispersion (Smyth et al. 1995). However, directed LOS links must be pointed prior to use, and require an uninterrupted line-sight path between the transmitter and the receiver, thus making them susceptible to blocking. In addition to this, by their very nature, they are more suited to point-to-point links rather than point-to-multipoint broadcast type links, thus reducing their flexibility. Directed LOS is the chosen configuration for IrDA links (IrDA 2001), which offer simple peer-to-peer networking between portable electronic devices such as laptops, palmtops, PDAs, and digital cameras. These devices are specified to operate over a maximum range of 1 m, and offer data rates from 9.6 kbps to 4 Mbps (IrDA 2001).

Non-directed LOS

The non-directed LOS configuration, Figure 3(b), uses wide beam transmitters and wide FOV receivers to achieve an increased coverage area and alleviate the need for pointing. In comparison with the directed LOS, these benefits are achieved at the expense of a reduced irradiance for a given range and transmit power. The use of wide-angle transmitters and receivers means that a portion of the received signal may have undergone one or more reflections from walls and room objects, thus giving rise to multipath propagation. Additionally, because the majority of power incidents on the photodetector are due to the LOS path, non-directed LOS links are still prone to blocking. Non-directed LOS links are well suited to point-to-multipoint broadcast type applications. A typical scenario for this link topology would be an OW access point located on the ceiling of a room, providing connectivity to the portable devices within its coverage area. Computer generated holograms have been proposed as a means of accurately defining the coverage area of non-directed LOS links (Smyth et al. 1995). Through control of the coverage area, large rooms may be divided into "optical cells", each serviced by a different infrared access port. Such architecture has been used in experimental systems (McCullagh and Wisely 1994) and proposed for a number of practical applications including telepoints (Nicholls, Greaves and Unwin 1996), trading desks, and desk area networks (Heatley and Neild 1999). Compared with the LOS, non-directed LOS systems are more susceptible to large dynamic variations of signal-to-noise ratio, leading to link failures. To overcome this problem, rate-adaptive transmission systems have been proposed that use repeated and punctured convolutional codes (Ohtsuki 2003) and angle diversity together with rate-adaptive transmission schemes (Tavares et al. 2003).

Diffuse

Exhibiting a similar behavior to that of visible light, infrared signals are absorbed by dark objects, diffusely reflected by light-coloured objects, and directionally reflected from shiny surfaces (Kahn and Barry 1997). Such characteristics have given rise to another link configuration referred to as the diffuse, see Figure 3(c), in which reflections from room boundaries are relied upon to provide coverage. This was first proposed in 1979 by Gfeller and Bapst. Typically, a diffuse transmitter points vertically upwards towards the ceiling, emitting a wide beam of infrared energy with an angular distribution given by the generalized Lambertian law as:

$$P(\theta) = \frac{n+1}{2\pi} P_t \cos^n \theta, \quad (5)$$

where, n is the Lambertian exponent, P_t is transmitted power, θ is the angle between the initial direction of light and the direction of maximum power. The receiver has a wide FOV, and collects the signal after it has undergone one or more reflections from the ceiling, walls, and objects in the room. Typical values for reflection coefficients are from 0.4 to 0.9 for white plaster walls, varying between

0.7 and 0.85 depending on surface texture and angle of incidence (Gfeller and Bapst 1979). From a user's point of view, the diffuse link topology is the most convenient because it does not require any pointing of the transmitter or receiver, nor does it require an LOS path to be maintained. In addition to this, the configuration is also extremely flexible, and can be used for both infrastructure and ad hoc networks (Street et al. 1997). However, along with non-directed LOS links, diffuse links requires relatively high optical power (~ 0.5 W) to illuminate the room. It also incurs a high optical path loss, which is typically in the range of 50–70 dB for a horizontal separation distance of up to 5 m (Kahn, Krause, and Carruthers 1995). The path loss is increased further if a person is standing next to the receiver such that the main signal path is obstructed, a situation referred to as shadowing. In addition to this, diffuse links must also contend with severe multipath propagation. Intersymbol interference (ISI) limits the maximum unequalized bit rate to ~ 260 Mbps (Gfeller and Bapst 1979). Thus, for a coverage volume of $10 \times 10 \times 3$ m, the unequalized bit rate would be limited to ~ 16 Mbps or higher (Smyth et al. 1995). Nevertheless, to date the diffuse configuration has received the greatest interest from the research community, and the number of experimental diffuse links has been reported covering bit rates up to 50 Mbps. Diffuse is also the chosen link configuration for the IEEE 802.11 infrared physical layer standard (IEEE Standard 802.11 1997), and diffuse systems are now commercially available (Spectrix 2000).

LOS with Tracking

Although diffuse links offer bit rates up to several tens of megabits per second, this is not adequate to support broadband applications such as video conferencing. For multi-user applications, there are basically two major schemes that can support very high bit rates. These are LOS links with tracking (Jungnickel et al. 2001), and the multiple-spot diffusing (MSD) scheme (Kavehrad and Jivkova 2003). The former, see Figure 3(d), offers high power efficiency and potentially high bit rates (> 100 Mbps) of directed LOS links, with the increased coverage enjoyed by non-directed LOS systems. In an early experimental tracked system developed by B.T. Labs, which achieved a bit rate of 1 Gbps, the tracking was performed using mechanical steerable optics (Wisely 1996). However, mechanical steerable optics are prohibitively expensive and difficult to miniaturize. Consequently, in the same paper, Wisely et al. proposed a solid state tracked system, using multi-element transmitter and receiver arrays along with a lens arrangement. Using this arrangement, steering is merely a matter of selecting the appropriate array element. Note that along with diffuse links using multi-beam transmitters and angle-diversity receivers, tracked systems offer the potential to implement space-division multiplexing, whereby multiple users can communicate without suffering a loss of per-user capacity, because each user is located in a different cell.

Kavehrad and Jivkova (2003) have shown that the use of MSD with a multi-beam transmitter and angle diversity receiver (see Figure 4), results in a significant improvement in system performance and higher data rates

Figure 4: Multi-spot diffusing configuration

can be achieved by covering the entire ceiling of a room with a regular grid of diffusing spots to ensure uniform distribution of optical power as well as roaming capability. Each diffusing spot can be created using a separate laser source and a lens; however it is rather complex to create a large number of diffusing spots. Alternatively, diffusing spots can be created using the holographic technique with a single laser source (Pakravan, Simova and Kavehrad 1997). However, the technique results in non-homogeneous distribution of optical power. This problem could be overcome by employing computer-generated holograms, where wavefronts produced will have prescribed amplitude and phase distributions. The hologram cell patterns, lattice spacing is given as (Kavehrad and Jivkova 2003):

$$\Delta S = \lambda ht - r/\Lambda, \quad (6)$$

where, Λ is the cell size and $ht-r$ is the height between transmitter and reflecting surface.

For non-directed LOS and diffuse links, significant performance improvements can be achieved using an angle-diversity receiver rather than a single element detector. This may be implemented in one of two ways. A non-imaging angle-diversity implementation consists of multiple receiving elements that are oriented in different directions, each element having its own non-imaging concentrator. The main drawback of this approach is that it can lead to an excessively bulky and costly receiver. A more elegant implementation is the imaging angle-diversity receiver, the so-called “fly-eye receiver,” first proposed by Yun and Kavehrad (1992), which consists of an imaging optical concentrator (e.g., a lens) with a segmented photodetector array placed at its focal plane. Regardless of the implementation method, the photocurrent generated by each element is amplified separately and may then be processed in a variety of ways, which vary in terms of performance and complexity. Angle-diversity receivers can simultaneously achieve a high optical gain and

a wide field of view. By exploiting the fact that unwanted signals are generally received from different directions than that of the desired signal, they can significantly reduce the effects of ambient light noise, co-channel interference, and multipath distortion. A further improvement in the power efficiency of diffuse links can be achieved by replacing the single wide-beam diffuse transmitter with a multi-beam transmitter, sometimes referred to as a quasi-diffuse transmitter, which consists of multiple narrow beams pointing in different directions (Yun and Kavehrad 1992).

Hybrid configuration based on diffuse and tracked links exploits the advantages of both schemes. In this configuration the tracked system is used all the time, provided a direct path exists between transmitter and receiver. When the path is blocked, the system switches to the diffuse back-up link until the direct path is established once more (see Figure 5). In order to ensure a distortion-free communication link, a receiver with direction diversity narrow FOV should be used. Narrow FOV results in significantly

Figure 5: Hybrid diffuse and tracked LOS links

reduced received optical power at the receiver compared with the ambient light.

Therefore, to improve the signal-to-noise ratio (SNR), an optical filter together with an optical concentrator should be used prior to detection. The total SNR is defined by:

$$SNR_T = \sum_{i=1}^N SNR_i, \quad (7)$$

$$SNR_T = \frac{[P_t R H_i(0)]^2}{N_{oi} R_b},$$

where, N is the number of receiver branches, P_t is the optical signal power, $H_i(0)$ is the path loss at the i^{th} receiver branch, and N_{oi} and R_b are the noise variance and data rate, respectively. It is shown that with the use of a holographic receiver front-end, the path loss is 6 dB lower and the SNR is 11 dB larger than with a bare receiver. Note that in contrast to conventional channels, where the SNR is proportional to the first power of the received average power, in optical systems the SNR is proportional to the square of the received optical average power, implying that for IM/DD optical links P_t must be relatively high and it can tolerate only a limited path loss.

STANDARDS AND EYE SAFETY

There are several "Infrared Data Association" IrDA (IrDA 2006) standards in existence today, covering a wide range of bit rates from 9.6 kbps to 4 Mbps. However, all links require an LOS and are only specified to work over a one meter range. For OW LANs, the IEEE 802.11 standard specifies three physical layers, two using radio with spread spectrum modulation and one using IR in the 780–950 nm wavelength range, and bit rates of 1 or 2 Mbps using diffuse propagation (IEEE 1997). However, radiation in this wavelength can be focussed onto the retina, causing thermal damage. The eye safety limit is a function of the viewing time, wavelength, and apparent size of the optical source. The standard makes a distinction between point sources (on which the eye can focus) and large area sources, which form an extended image on the retina. The standard treats laser and LED sources equally. For modulated optical sources, generally, the average power level limits the transmitted optical power. In general, the average power for a pulse train of duration 100s must not exceed the power of a single

pulse of duration 100s. Table 2 shows the Class 1 power limits for both point and extended sources for a number of important wavelengths (Street et al. 1997). Here α is the angle subtended by the source at measurement point and MPE is equal to power captured by a 50 mm diameter aperture 100 mm from the optical detector.

CHANNEL CHARACTERISTICS

The power penalties directly associated with the channel may be separated into two factors, these being optical path loss and multipath dispersion (Carruthers and Kahn 1996). For directed LOS and tracked configurations, reflections do not need to be taken into consideration, and consequently the path loss is easily calculated from knowledge of the transmitter beam divergence, receiver size, and separation distance. For non-directed LOS and diffuse links, the optical path loss is more complex to predict because, it is dependent on a multitude of factors such as room dimensions, the reflectivity of the ceiling, walls, and objects within the room, as well as the position and orientation of the transmitter and receiver, to name but a few. In order to predict the path loss for non-directed LOS and diffuse links, it is necessary to analyse the distribution of optical power for a given setup. Gfeller and Bapst (1979) studied the power distribution for diffuse links, basing their model on single reflections only. The authors showed that by using an optical source consisting of multiple elements oriented in different directions, a more uniform coverage can be obtained over a larger area, compared with a single wide-beam optical source. Light is emitted with Lambertian characteristics and at the receiver, light collected from all directions is summed. Barry et al. (1993) adopted a recursive algorithm to allow higher order reflections to be taken into account. Lomba, Valadas and Duarte (1993) addressed the optimization of the optical power distribution for diffuse and non-directed LOS links. Pakravan and Kavehrad (1995) also analysed the optical power distribution for a typical conference room using various link configurations.

While determining the distribution of optical power throughout a room is adequate for basic power budget calculations, it does not allow the power penalty due to multipath propagation to be accurately predicted, because multiple reflections are not taken into consideration. Although the optical power associated with two or more reflections is relatively small, the signal arrives at the receiver much later than that undergoing only one reflection, and hence, cannot be ignored when considering high-speed non-directed LOS and diffuse links. In

Table 2: Class 1 Source Maximum Permissible Exposure (MPE) Power Limits

Wavelength	Point Source MPE ($\alpha < \alpha_{min} = 0.011$ rad, exposure time > 1 s)	Extended Source MPE ($\alpha > \alpha_{max} = 0.1$ rad, exposure time > 1 s)
850 nm	0.44 mW	$0.8(\alpha_{max}/\alpha_{min})$ mW
980 nm	0.8 mW	$0.8(\alpha_{max}/\alpha_{min})$ mW

order to generate an impulse response which includes higher order reflections, Barry et al. (1993) developed a ray-tracing algorithm in which the path loss and time delay are calculated for every path containing a given number of reflections. The algorithm then sums together all contributions to give an overall impulse response. Abtahi and Hashemi (1995) modified this work to consider the effects of furniture and people within the room, and also rooms of irregular shape. Pakravan and Kavehrad (1995) used a neural network to speed up the algorithm developed by Barry, whereby only a fraction of the total number of points need to be calculated, from which the neural network learns the rest. Lomba, Valadas, and Duarte (2000) developed a computationally efficient ray-tracing algorithm which uses look-up tables and progressively decreased resolution to speed up the simulation. Lopez-Hernandez, Perez-Jimenez, and Santamaria (1998) also developed a computationally efficient algorithm based on Monte Carlo analysis, where a path of a single photon is tracked during a random flight in a room until it is detected by the receiver. Although ray tracing is a reliable technique, it is not as efficient as the Gfeller and Bapst. A different approach was taken by Carruthers and Kahn (1996), who developed the ceiling bounce model, based on the claim that realistic multipath infrared channels can be characterised by only two parameters, these being optical path loss $H(0)$ and root mean square (RMS) delay spread D_{rms} . The authors adopt a two stage modeling approach: first assuming an infinitely large room, i.e., considering only a single reflection from the ceiling, and then making a correction which takes into account the position of the transmitter and receiver within the room. Multipath delay spread occurs due to reflection from different surfaces and local scattering, giving rise to intersymbol interference. Multipath leads to pulse dispersion, and it can also occur in the LOS point-to-point configuration due to movement of people within the vicinity of the communication links. The channel impulse response defined in terms of a unit step function $u(t)$ is given as:

$$h(t, a) = H(0) \frac{6a^6}{(t + a)^7} u(t), \quad (8)$$

where, a depends on the room size and the locations of the transmitter and receiver. For co-located transmitter and receiver, $a = 2H/c$ where H is the height of the ceiling above the transmitter and receiver and c is the speed of light. The delay spread is also related to as:

$$D_{rms} = \frac{a}{12} \left(\frac{13}{11} \right)^{0.5}. \quad (9)$$

For a given channel characteristics, H_0 , P_e and R_b , and a modulation scheme the power and D_{rms} are normally defined in terms of their normalised values. For power it is defined as $P_i/P_{OOK-ideal}$ and the normalised D_{rms} is defined as $D_T = D_{rms}R_b$. Here, $P_{OOK-ideal}$ is the power of the system using on-and-off keying (OOK) on ideal channel. In indoor OW systems, because the room configuration

is fixed, the link with IM/DD could be considered as a linear time variant, and linear equalisation schemes, spread spectrum techniques, coding, antenna diversity and directivity, and polarization techniques could be employed to compensate for any multipath dispersion.

OPTICAL COMPONENTS

Optical Sources

From a commercial point of view, the wavelength band between 780 and 950 nm is currently the best choice for most infrared applications due to the availability of low cost light-emitting diodes (LEDs) and laser diodes (LDs), and because it coincides with the peak responsivity of inexpensive silicon photodetectors. However, electromagnetic radiation in this band can cause damage to the human eye, and is therefore subject to eye safety regulations. The standard on laser safety contains a number of classifications, the lowest power of which is Class 1, implying that a device is safe under all foreseeable circumstances of use. The classification limits are dependent on a number of parameters, these being wavelength, apparent source size, pulse duty factor, and exposure duration. The standard treats LD and LED sources equally, the only difference being that LDs are generally categorised as point sources, which can be focussed to a small area on the retina, whilst LEDs usually fall under the extended source category, and form a larger image on the retina. From a power budget point of view, the wavelength band around 1.5 μm would be a much better choice, because the safety standard permits larger optical transmit powers to be used, and as shown in Figure 6, ambient light sources emit less power at these wavelengths. However, the major drawback to operating at such wavelengths is the lack of low cost optoelectronic devices available at present. The choice of optical source is largely dependent on the cost and performance. LEDs benefit from low cost and simple drive circuitry, but suffer from poor electrical-to-optical conversion efficiency, limited bandwidth, and broad spectral width (typically 40 nm), which prevents the use of narrow-band optical filters at the receiver. In contrast, LDs are more costly and require more complicated drive circuitry, but offer a number of advantages such as improved conversion efficiency, wide modulation bandwidth, and narrow spectral width, thus making them the obvious choice for high speed links. In terms of eye safety, LEDs are generally supplied in a lensed package and do not require any additional components to make them eye safe. Laser diodes, on the other hand, are essentially point source devices and must be diffused using computer generated holograms and/or integrating sphere diffusers in order to be classified as eye safe.

Photodetectors

The photodetector used in an IR system must have high responsivity to maximise the system power margin and wide bandwidth to allow for high data rates. There are two types of photodetectors: the positive-intrinsic-negative (PIN) photodiode and the avalanche photodiode (APD). The APDs achieve a very good performance when the

Figure 6: Optical power spectra of common ambient light sources

ambient light is very low, i.e., for LOS systems. However, in non-directed links, particularly diffuse links, where shot noise due to ambient light is dominant, the gain achieved by APDs decreases the SNR because the random nature of the APD's internal gain increases the variance of the shot noise by a factor greater than the signal gain (Kahn and Barry 1997). PIN photodiodes are preferable to APDs for use in non-directed links (Kahn and Barry 1997), offering low-cost, and large surface area, which results in improved signal-to-noise ratio (SNR) because the received signal power increases linearly with the area, while the noise power increases with its square root.

Optical Concentrators and Filters

Optical wireless receivers generally employ some form of optical concentrator in order to increase the effective area of the detector. High gains can be achieved using compound parabolic concentrators, but these devices have a narrow FOV and are therefore limited to use in directed links. Non-directed links generally make use of a hemispherical lens, which achieves a wide FOV and an omni-directional gain (Kahn and Barry 1997; Street et al. 1997). Optical filtering is also generally used to attenuate the out-of-band background radiation. Two basic types of optical filters exist; these being long-pass filter (LPF) and band-pass filter (BPF). LPFs are generally constructed of colored glass, and pass all wavelengths longer than a specified cut-on wavelength (Kahn and Barry 1997). In conjunction with a silicon PIN photodiode, which typically has a sensitivity range from 400 nm to 1.1 μm , LPFs result in a band-pass response with a spectral width on the order of several hundred nanometers. In contrast, BPFs, also referred to as interference filters, are constructed of multiple layers, and can achieve extremely narrow bandwidths. Such filters can be extremely effective when used in conjunction with LDs. However, one of the characteristics of BPF is that the pass band shifts as the angle of incidence changes. Therefore, this can result in a narrowing of the FOV, which may be unacceptable in non-directed links. This problem can be solved by bonding the band pass filter to the curved surface of a hemispherical lens (Spectrix 2000).

Preamplifier

A transimpedance amplifier is the best choice as a preamplifier stage at the receiver because it achieves a wide bandwidth and large dynamic range without the need for equalisation (Kahn and Barry 1997; Street et al. 1997; Phang and Johns 1999). The large dynamic range is important to accommodate variable link distances. The choice between employing a field-effect transistor (FET) or a bipolar-junction transistor (BJT) in the preamplifier depends on many factors. For example, FETs achieve low noise at high bit rates but suffer from relatively low transconductance, while BJTs achieve higher transconductances leading to better power conception (Kahn and Barry 1997; Street et al. 1997).

Ambient Light Sources

Artificial sources of ambient light introduce a periodic interference signal in optical wireless receivers which, if ignored, has the potential to degrade link performance. The three main sources of ambient light are sunlight, incandescent lamps, and fluorescent lamps and their optical power spectra are shown in Figure 6. Note that the spectra have been scaled to have equal maximum value, and the longer wavelength region of the fluorescent lamp spectrum has been amplified by a factor of 10 in order to make it clearly visible. When present, direct sunlight is typically much stronger than the other two sources, and represents an unmodulated source of ambient light with a very wide spectral width and a maximum power spectral density located at ~ 500 nm. All artificial ambient light sources are modulated, either by the mains frequency or, in the case of some fluorescent lamps, by a high-frequency switching signal.

Incandescent Lamp. Incandescent lamps have a maximum power spectral density around 1 μm , and produce an interference signal which is a near-perfect sinusoid with a frequency of 100 Hz. With this source, only harmonics up to 400 Hz carry a significant amount of power, and beyond that, all harmonics are more than 60 dB below the fundamental. The average received photocurrent I_B and

Table 3: I_B and I_{pk-pk} for Incandescent Bulb with and without Optical Filtering

	Without Optical Filter	With Optical Filter	Reduction
I_B	100 μ A	20.5 μ A	79.5 %
I_{pk-pk}	65.2 μ A	12 μ A	81.6 %
I_B/I_{pk-pk}	1.53	1.71	

Table 4: I_B and I_{pk-pk} for Low and Frequencies Fluorescent Lamp with and without Optical Filtering

	Without Optical Filter		With Optical Filter		Reduction	
	Low Frequency	High Frequency	Low Frequency	High Frequency	Low Frequency	High Frequency
I_B	100 μ A	100 μ A	5.4 μ A	3.9 μ A	94.6 %	96.1 %
I_{pk-pk}	67.7 μ A	33.6 μ A	9.6 μ A	4.9 μ A	85.8 %	85.4 %
I_B/I_{pk-pk}	1.48	2.98	0.56	0.80		

peak-to-peak interference signal photocurrent I_{pk-pk} for a 60 W incandescent bulb are given in Table 3. With optical filtering, I_B is reduced by 79.5 %, and the peak-to-peak amplitude of the interference signal is reduced by 81.6 %. The ratio of I_B/I_{pk-pk} is fairly similar both with and without optical filtering.

Fluorescent Lamp Driven by Conventional Ballast. Low frequency fluorescent lamps are driven by the mains frequency. For the low-frequency fluorescent lamps (Ballast – Crompton C237 1 \times 75W and tube – Osram L 70W/23), the average received photocurrent and peak-to-peak interference signal photocurrent are given in Table 4. Optical filtering gives a significant reduction in both the average background photocurrent and the peak-to-peak interference amplitude. Because the reduction in I_B is greater than the reduction in I_{pk-pk} , with the optical filter in place, the peak-to-peak variation of the photocurrent is actually greater than the average background photocurrent.

Fluorescent Lamp Driven by Electronic Ballast. Fluorescent lamps driven by high-frequency electronic ballasts have a number of advantages over their low frequency counterparts, such as reduced electrical power consumption for a given level of illumination and increased life-expectancy of the tubes. The actual switching frequency used varies from one manufacturer to another, but is typically in the range 20–40 kHz. Its spectrum contains harmonics of the switching frequency and also harmonics of the mains frequency, similar to low frequency fluorescent lamps. Harmonics of the switching frequency can extend into the MHz range, and therefore present a much more serious impairment to optical wireless receivers. The average received photocurrent and the peak-to-peak

interference signal photocurrent are given in Table 4. Without optical filtering, for a given background photocurrent, the interference amplitude produced by the high-frequency fluorescent lamp is only about half that produced by the low-frequency fluorescent lamp. Optical filtering gives a similar reduction in I_B and I_{pk-pk} as it did for the low-frequency fluorescent lamp.

MODULATION SCHEMES

Selecting a modulation technique is one of the key technical decisions in the design of any communication system. Before selection can take place, it is necessary to define the criteria on which the various modulation techniques are to be assessed. For the indoor OW channel, the main criteria are power efficiency and bandwidth efficiency, which will be discussed here.

Power Efficiency. In order to comply with eye safety regulations, the average optical power emitted by an optical wireless transceiver is limited, as expressed in (4). Furthermore, in portable battery powered equipment, it is desirable to keep the electrical power consumption to a minimum, which also places limitations on the optical transmit power. Consequently, power efficiency is the most important criterion when evaluating modulation techniques suitable for indoor optical wireless communication systems. Thus, different schemes are usually compared in terms of the average optical power required to achieve a desired bit error rate (BER) at a given data rate.

Bandwidth Efficiency. When shot noise is dominant, generally the received SNR is proportional to the photodetector area. Consequently, single element receivers favor the use of large area photodetectors. However, the high

capacitance associated with large area photodetectors has a limiting effect on receiver bandwidth. In addition to this, for non-directed LOS and diffuse link configurations, the channel bandwidth is limited by multipath propagation. Therefore, it follows that modulation schemes which have a high bandwidth requirement are more susceptible to intersymbol interference, and consequently incur a greater power penalty. Thus, bandwidth efficiency is the second most important criterion when evaluating modulation techniques.

There are other considerations, such as cost and complexity for mass-market applications. Achieving excellent power efficiency and/or bandwidth efficiency is of little use if the scheme is so complex to implement that cost renders it unfeasible. Another consideration when evaluating modulation techniques is the ability to reject the interference emanating from artificial sources of ambient light. The simplest method to achieve this for the baseband schemes is to use electrical high-pass filtering. Consequently, it is desirable that the chosen modulation technique does not have a significant amount of its power located at DC and low frequencies, thereby reducing the effect of baseline wander and thus permitting the use of higher cut-on frequencies. In addition to this, if the chosen modulation technique is required to operate at medium to high data rates over non-directed LOS or diffuse links, then multipath dispersion becomes an issue. Thus, it is also desirable that the scheme be resistant to ISI resulting from multipath propagation.

For the IM/DD indoor OW channel, candidate modulation techniques can be grouped into two general categories, these being the baseband and sub-carrier modulation (SCM) (also known as multiple-sub-carrier modulation) schemes. In SCM, multiple digital streams are multiplexed in the RF domain and modulated onto a single wavelength optical carrier signal using intensity, phase, or frequency modulation. The IM/DD is the simplest and the cheapest option. SCM is more bandwidth efficient than its counter part the single-carrier modulation and it allows transmission with minimal ISI on frequency selective and multipath channels, thus offering realization of high-speed communications (Ohtsuki 2003). A particularly attractive scheme that uses multiple carriers overlapped in the frequency domain is known as the orthogonal frequency division multiplexing (OFDM), capable of supporting high data rates without the need for channel equalisers (Gonzalez et al. 2006). But SCM schemes are less power efficient than pulse modulation techniques because of inclusion of a DC offset in order to satisfy the requirement that $x(t)$ cannot be negative, as expressed in (4).

There is a range of modulation schemes such as analogue, digital, and baseband modulation techniques that are used in OW communications. Here the latter, which includes OOK and the family of pulse time modulation techniques, will be highlighted. There are many different types of modulation schemes, each with its particular advantages and disadvantages, and experimental and analytical performance of these modulation schemes have been extensively studied by a number of researchers (Barry 1994; Kahn and Barry 1997; McCullagh and Wisely 1994; Wong, O'Farrell, and Kiatweerasakul 2000; and

Ghassemlooy, Hayes, and Wilson 2003). Because the average optical power emitted by an IR transceiver is limited, the performance of modulation techniques is compared in terms of the average received optical power required to achieve a desired BER at a given data rate.

OOK

Of all the various modulation schemes for IM/DD, OOK is the simplest and the most commonly used, where a zero and a one are represented by zero intensity and some positive intensity, respectively as shown in Figure 7. OOK can use either non-return-to-zero (NRZ) or return-to-zero (RZ) pulse formats. OOK-RZ (with reduced pulse duration) is more power efficient than OOK-NRZ but requires more transmission bandwidth. The detailed performance analysis of OOK on AWGN channel can be found in (Barry 1994; and Kahn and Barry 1997). The OOK with return-to-zero-inverted (RZI) signalling format has been used in commercial IrDA based devices operating below 4 Mbps.

Pulse Position Modulation (PPM)

PPM is a good alternative to OOK to provide better power efficiency at the cost of reduced bandwidth efficiency. In PPM, M bits input data are mapped to one of L possible symbols, where $L = 2^M$; see Figure 7. Each symbol consists of a pulse occupying one slot and $L-1$ empty slots. The information is encoded by the position of the pulse within the symbol. By increasing the number of bits per symbol, the power efficiency of the code is improved at the expense of the bandwidth efficiency. PPM has been used widely in OW systems and is also adopted for the IEEE 802.11 infrared physical layer standard and IrDA serial data links operating at 4 Mbps. There are several types of PPM, such as differential PPM (Shiu and Kahn 1999), multiple PPM (Parker and Barry 1996), and differential amplitude PPM (Sethakaset and Gulliver 2004). In addition to these, coded schemes such as convolutional-coded PPM and trellis-coded overlapping PPM also exist, each with its own advantages and disadvantages. Compared with OOK, PPM does increase system complexity because both slot and symbol synchronizations are required in the receiver. Table 7 compares OOK-NRZ, OOK-RZ, and PPM in terms of both power and bandwidth efficiencies. The power efficiency is defined by the required transmitted power to achieve a target BER, and the bandwidth efficiency is defined as zero-crossing bandwidth ($R_b = 1/\text{pulse width}$). Modulation schemes with a much wider pulse width (e.g., OOK-NRZ) are the least power efficient, but are bandwidth efficient. Bandwidth efficient modulation schemes offer advantages such as resilience to multipath distortion and less complex system implementation. For a given bandwidth efficiency, the PPM is the more power efficient; however, it is more susceptible to multipath-induced intersymbol interference. Uncoded PPM employing optimal maximum-likelihood sequence detection (MSLD) and sub-optimum equalization still suffers from larger ISI penalties than OOK. However, coding (e.g., Trellis) could be used to effectively mitigate the effects of ISI.

Figure 7: OOK, PPM, DPIM, and DH-PIM symbol structure

Digital Pulse Interval Modulation (DPIM)

In each PPM symbol with a fixed length, the empty slots following a pulse are essentially redundant, and with the removal of these redundant slots the symbol length thus becomes variable, thus leading to digital pulse interval modulation (DPIM). In DPIM, information is encoded by varying the number of empty slots between adjacent pulses (Ghassemlooy and Hayes 2000). As with L -PPM, L -DPIM maps each block of $M = \log_2 L$ input bits to one of L possible symbols (see Figure 7). Unlike L -PPM, however, symbol durations are variable and determined by the information content of each particular symbol. In order to avoid symbols, which have no slots between adjacent pulses, guard slots may be added to each symbol immediately following the pulse. Thus, each symbol consists of a pulse of constant power with duration less than one slot T_s , followed by k empty slots, where $1 \leq k \leq L$. The minimum and maximum symbol durations are $2T_s$ and $(L + 1)T_s$, respectively. In L -PPM, each symbol has a fixed duty cycle of $1/L$, whereas in L -DPIM symbols have a variable duty cycle with the average length higher than $1/L$. Consequently, for a fixed value of L , DPIM has a higher average power requirement compared with PPM. In L -PPM, the slot rate is given as $R_s = LR_b/M$, where R_b is the OOK bit rate. In L -DPIM, there are two options for the slot rate, as discussed in the following sections.

Dual Header Pulse Interval Modulation (DH-PIM)

The characteristics of OW systems can be further exploited by modifying the DPIM into the DH-PIM, which

has a shorter symbol length, thus resulting in increased transmission capacity and improved bandwidth at the cost of slightly reduced power efficiency (Aldibbiat, Ghassemlooy, and McLaughlin 2001). Also DH-PIM offers built-in symbol synchronization, relatively straightforward slot synchronization, and improved immunity to the multipath dispersion at high dispersive medium compared with DPIM. DH-PIM is an asynchronous scheme with a symbol composed of a header followed by a number of blank time slots signifying the signal information; see Figure 7. The header can take one of two different states (H_1 or H_2), depending on the pulse duration. In H_1 and H_2 , the pulse durations are $\alpha T_s/2$ and αT_s , respectively. The number of information slots $d_n \in \{0, 1, \dots, 2^{M-1} - 1\}$ is variable and depends on the binary value of the input data (M -bit). If the most significant bit of the input data is 0, then d_n is equal to the decimal value of the input data; otherwise it is equal to the decimal value of the 1's complement of the input data.

Performance

The performance of the optical wireless system defined in terms of SNR is given as:

$$SNR = \frac{(P_t H(0) R)^2}{N_0 R_b} \quad (10)$$

where, N_0 and R_b are the noise variance and data rate, respectively. Note that the SNR is a function of the square power; thus OW systems will naturally require high transmitted power and limited path loss compared to the

Table 5: Energy Per Pulse and Bandwidth Requirements for OOK, PPM, DPIM, DH-PIM

Modulation Type	Energy Requirement/Pulse	Bandwidth Requirement B_{req}
OOK-NRZ	$(RP_{ave})^2/R_b$	R_b
OOK-RZ $_{\alpha}$	$(RP_{ave})^2/\alpha R_b$	R_b/α
PPM	$LM(RP_{ave})^2/R_b$	$2^M R_b/M$
DPIM	$L_{ave}M(RP_{ave})^2/R_b$	$(2^M + 3)R_b/2M$
DH-PIM	$16ML_{ave}(RP_{ave})^2/9\alpha R_b$	$(2M^{-1} + 2\alpha + 1)R_b/\alpha M$

**Figure 8:** Optical power requirements for OOK, PPM, DPIM, DH PIM1, and DH PIM2 normalized to OOK-NRZ against bandwidth requirement normalized to the bit rate for different bit resolution (i.e., $M = \log_2 L$)

electrical systems. These differences have a profound effect on system design. On conventional channels, the SNR is proportional to the average received power, whereas on optical wireless links, it is proportional to the square of the average received optical signal power; thus implying that relatively high optical transmit powers are required, and only a limited path loss can be tolerated. The fact that the average optical transmit power is limited suggests that modulation techniques possessing a high peak-to-mean power ratio are favorable. This is generally achieved by trading off power efficiency against bandwidth efficiency. When the shot noise is dominant, the SNR is also proportional to the photodetector area. Thus, single element receivers favour the use of large area detectors. However, as the detector area increases so does its capacitance, which has a limiting effect on receiver bandwidth. This is in direct conflict with the increased bandwidth requirement associated with power efficient modulation techniques, and hence, a trade off exists between these two factors.

Table 5 shows the energy and bandwidth requirement for a number of modulation schemes. The bandwidth requirement, defined as the span from DC to the first null in the power spectral density (PSD) of the transmitted waveform, is also normalized to OOK. The average optical power requirement versus bandwidth requirement for OOK, PPM, DPIM and DH-PIM are shown in Figure 8.

CONCLUSION

The combination of a need for effective short-range indoor OW connectivity, ample unlicensed bandwidth, relative security, and a high transmission rate at a low cost makes an OW link preferable to the RF link in many applications. In this chapter, an overview of OW for indoor application was introduced. A number of IR wireless link configurations were introduced, each suitable for different applications. In terms of system design, the limitations directly imposed by the channel, such as the path loss and dispersion, are largely dependent on the chosen

link configuration. For example, LOS links have a small path loss and do not suffer from multipath propagation. However, in order to achieve a degree of mobility, it is necessary to use a tracked configuration, but that greatly increases cost and complexity of the system. In contrast, non-directed links offer some mobility without increasing system complexity, but ought to overcome high path loss and multipath propagation. Indoor IR links are required to operate in the presence of intense ambient light. Along with contributing to the generation of shot noise, artificial ambient light also introduces a periodic interference signal in optical receivers. Of all the artificial ambient light sources, the fluorescent lamps driven by electronic ballasts are potentially the most detrimental to system performance because their detected electrical spectrum can contain harmonics into the MHz region. The extent to which ambient light sources affect link performance is also dependent, to a degree, on the chosen link configuration. Due to the directional nature of their transmitters and receivers, directed links can reject much of the background radiation, while non-directed links are more susceptible to it. Irrespective of the chosen link configuration, the indoor optical wireless channel is unique, combining the filtered Gaussian noise characteristics of conventional wire-based channels with the IM/DD constraints of fiber-optic systems. From a system design point of view, the diffuse configuration suffers the most severe channel parameters and consequently presents the greatest challenge to achieving robust, high-speed communication. As for the modulation techniques, there are a number of options, each offering its own advantages and disadvantages in terms of power and bandwidth efficiencies, and system complexity.

GLOSSARY

Ambient Light: In an optical wireless system, it is the light (due to sun, and man-made sources) that illuminates a room or a detector.

Average Power: The power averaged over a cycle of an electromagnetic signal.

Channel: A path for conveying electromagnetic signals (electrical or optical) from a source to a destination.

Diffuse Reflection: Reflection from a surface which may not maintain the integrity of the incident wavefront.

Dispersion: Any process by which an electromagnetic signal (electrical or optical) propagating through a physical channel is corrupted because different frequencies/wavelengths of the signal have different propagation velocities within the physical channel.

Fading: The variation (with time) of the amplitude or relative phase, or both, of one or more of the frequency components of the received signal.

Field of View (FOV): The angular size of an optical source being viewed by a photodetector.

Intensity Modulation: The intensity (amplitude) of light being directly modulated by the input data.

Intersymbol Interference: The distortion manifested in the temporal spreading and consequent overlap of individual pulses, to the degree that the receiver cannot reliably distinguish between individual signal elements.

Lambertian Source: An optical source with an intensity directly proportional to the cosine of the angle from which it is viewed.

Modulation: The process of varying a characteristic of a high frequency carrier signal in accordance with a low frequency information signal.

Multipath: The propagation phenomenon that results in electromagnetic signals' reaching the receiver by two or more paths.

Optic Filter: Transmits or blocks a range of wavelengths, polarizations, etc., or selectively displaces an optical beam.

Path Loss: The attenuation undergone by an electromagnetic signal when propagating through a communication channel (or medium). Attenuation usually expressed in dB.

Photocurrent: The current that flows through a photodiode, as the result of exposure to optical radiant power.

Photodetector: A semiconductor device that converts an optical power into an equivalent electrical signal containing the same information.

Pulse Interval Modulation (PIM): Modulation in which the temporal intervals of the pulses are varied in accordance with some characteristic of the modulating data.

Pulse-Position Modulation (PPM): Modulation in which the temporal positions of the pulses are varied in accordance with some characteristic of the modulating data.

Responsivity: In a photodetector, the ratio of the electrical output to the optical input (usually expressed in A/W).

Shot Noise: The noise caused by random fluctuations in the motion of charge carriers, also defined as the fluctuation in the number of photons, which results in a random photo-current.

Signal-to-Noise Ratio (SNR): The ratio of the amplitude or power of the desired signal to the amplitude or power of noise signals at a given point in time.
